# Chapter 1

## Introduction

Software bugs are an inherent part of programming, often leading to unexpected behaviour and system failures. Debugging these errors is a *time-consuming process* taking between 20-60% of active work time [16], with programmers spending a *highly skewed* proportion of their time identifying and resolving a small proportion of *difficult* bugs [11].

Type systems aim to alleviate some of this burden by classifying expressions and operations that are allowed to work on them. This may be done *statically* at compile time or *dynamically* during runtime. The expressions not conforming to the type system manifest themselves as *type errors*.

In static typing, blame for type errors are typically localised to a *single* location in the code. However, this localisation may be misleading, as the actual cause of the error might be rooted in a broader context, for example in OCaml 65% of type errors related to *multiple* locations [17]. This is a particularly prevalent issue in *type inferred* languages.

In dynamic typing, type errors are often missed as they only appear during runtime with specific inputs. Additionally, they don't generally specify any source code context which caused them. Instead, a dynamic type error is accompanied by an *evaluation trace*, which can be *more intuitive* [29] by demonstrating concretely why values are *not* consistent with their expected type as required by a *runtime cast*.

This project seeks to improve user understanding of type errors by localising static type errors *more completely*, and *combining* the benefits of static and dynamic type errors.

I consider three research problems and implement three features to solve them in the Hazel language [1].<sup>1</sup>

1. Can we statically highlight code which explains *static type errors* more *completely*, including all code that *contributes* to the error?

This would alleviate the issue of static errors being *incorrectly localised*, and help give a *greater context* to static type errors.

**Solution:** I devise a *novel* method of **type slicing** including formal mathematical foundations built upon the formal *Hazel calculus* [15]. Additionally, it generalises to highlight all code relevant to typing *any* expressions (not just erroneous expressions).

2. Can we dynamically highlight source code which contributes to a *dynamic type error*?

---

<sup>1</sup>The answers may differ greatly for other languages. Hazel provides a good balance between complexity and usefulness.

**Figure 1.1:** A Static Type Error

This would provide missing source code context to understand how types involved in a dynamic type error originate from the source code.

**Solution:** I devise a *novel* method of **cast slicing**, also with formal mathematical foundations. Additionally, it generalises to highlight source code relevant to requiring any specific *runtime casts*.

3. Can we provide dynamic *evaluation traces* to explain *static type errors*?

This would provide an *intuitive* concrete explanation for static type errors.

**Solution:** I implement a **type error witness search procedure**, which discovers inputs (witnesses) to expressions which cause a *dynamic type error*. This is based on research by Seidel et al. [20] which devised a similar procedure for a subset of OCaml.

Hazel [1] is a functional locally inferred and gradually typed research language allowing the writing of *incomplete programs* under active development at the University of Michigan.

**INTRODUCE HAZEL & IT'S VISION HERE WITH IT'S BASIC UNUSUAL FEATURES & Show why it is a good choice to answer the research questions for.**

(i.e. a notebook environment, easy teaching language for students, teaching language to understand complex type systems... All are situations where better error explanations are useful (**cite that students struggle more with type errors**))

These three features *work well together* in Hazel to allow *both* static and dynamic type errors to be explained to a *greater extent* than in any existing languages. Arguably, these explanations are *intuitive*, and should help reduce debugging times and aid in students understanding type systems.<sup>2</sup>

For example, here is a basic walk-through for how a static type error could be diagnosed using the three features.

**MAP function? show a static error version Reference to detailed analysis in the evaluation section.**

## 1.1 Related Work

There has been extensive research into attempting to understand *what* is needed [24], *how* developers fix bugs [13], and a plethora of compiler *improvements* and *tools* **add citations here, primarily functional language tools**. This project builds upon this body of research in new ways focusing on the Hazel language, which is itself a research project being taken in various directions (**cite the directions**) but generally as a *teaching language* (**cite the explainthis paper**) for students.

To my knowledge the ideas of *type slicing* and *cast slicing* are novel. However, they do output *program slices* which were originally explored by Weiser [55], though my definition of program slices matches more with functional program slices [28]. The properties I explore are more similar to *dynamic program slicing* [52] but with type characteristics rather than evaluation characteristics, in a sense similar *type error slicing* [41].

---

<sup>2</sup>Proving this would require a user study.

The *type witness search procedure* is based upon Seidel et al. [20], though there are significant differences in workings due to my use of Hazel and various extensions as compared to the subset of OCaml used by Seidel et al.

## 1.2 Dissertation Outline

Chapter 2 introduces the *type theories* (section 2.1.1) underpinning the *Hazel core calculus* (section 2.1.2), followed by basic background on the *Hazel implementation* (section 2.1.3). Additionally, methods of non-deterministic programming are introduced (section 2.1.4).

Section 3.1 and section 3.2 formalise and prove<sup>3</sup> the ideas of *type slices* and *cast slices* in the Hazel core calculus.

An implementation (section 3.3-3.4) of these has been created covering *most*<sup>4</sup> of the Hazel language, including a user interface.

A *type witness search procedure* was successfully implemented. This involved creating a *hole instantiation* and a simplified *hole substitution* method (section 3.6.4); there is currently no full hole substitution feature in Hazel despite it's presence in the core calculus (section 2.1.2). Additionally, a customisable instantiation method was implemented (??) controllable via a UI.<sup>5</sup>

The slicing features and search procedure met all goals, **list eval goals briefly**, showing *effectiveness* (section 4.4) and being reasonably *performant* (section 4.5) over a corpus of *well-typed* and *ill-typed* Hazel programs respectively (section 4.3). Further, considered deviations from the slicing theories and strengths and weaknesses of the search procedure were evaluated in detail (section 4.6). A cognitive walk-through is performed in section 4.7 considering the use of all the features in debugging the static type error presented in the introduction in ??.

Finally, further directions and improvements have been presented along with discussion on the applicability of these features, slicing in particular, to real world debugging situations in chapter 5.

<sup>3</sup>TODO

<sup>4</sup>Except for type substitution.

<sup>5</sup>TODO

# Chapter 2

## Preparation

In this chapter I present the technical background knowledge for this project: an introduction to the type theory for understanding Hazel’s core semantics, an overview of Hazel implementation, and notes on non-determinism (as the type witness search procedure is non-deterministic). Following this, I present my software engineering methodology.

### 2.1 Background Knowledge

#### 2.1.1 Static Type Systems

A *type system* is a lightweight formal mathematical method which categorises values into *types* and expressions into types that evaluate to values of the same type. It is effectively a static *approximation* to the runtime behaviour of a language.

##### Syntax

Trivial, probably not needed? Cite BNF grammars etc. All Ib stuff. Maybe briefly show examples of Lambda calculus-like syntax?

##### Judgements & Inference Rules

A *judgement*,  $J$ , is an assertion about *expressions* in a language [19]. For example:

- $\text{Exp } e - e$  is an *expression*
- $n : \text{int} - n$  has type *int*
- $e \Downarrow v - e$  evaluates to *value*  $v$

While an *inference rule* is a collection of judgements  $J, J_1, \dots, J_n$ :

$$\frac{J_1 \quad J_2 \quad \dots \quad J_n}{J}$$

Representing the *rule* that if the *premises*,  $J_1, \dots, J_n$  are true then the conclusion,  $J$ , is true. When the collection of premises is empty, it is an *axiom* stating that the judgement is *always* true. Truth of a judgement  $J$  can be assessed by constructing a *derivation*, a tree of rules where it’s leaves are axioms. It is then possible to define a judgement as the largest judgement that is

*closed* under a collection of rules. This gives the result that a judgement  $J$  is true *if and only if* it has a derivation.

Properties on expressions can be proved using *rule induction*, if a property is *preserved* by every rule for a judgement, and true for it's axioms, then the property holds whenever the judgement is derivable.

A *hypothetical judgement* is a judgement written as:

$$J_1, \dots, J_n \vdash J$$

is true if  $J$  is derivable when additionally assuming each  $J_i$  are axioms. Often written  $\Gamma \vdash J$  and read  $J$  *holds under context*  $\Gamma$ . Hypothetical judgements can be similarly defined inductively via *rules*.

## Defining a Type System

A typical type system can be expressed by defining the following hypothetical judgement form  $\Gamma \vdash e : \tau$  read as *the expression  $e$  has type  $\tau$  under typing context  $\Gamma$*  and referred as a *typing judgement*. Here,  $e : \tau$  means that expression  $e$  has type  $\tau$ . A *typing context*,  $\Gamma$ , is a list of types for variables  $x_1 : \tau_1, \dots, x_n : \tau_n$ . For example the SLTC<sup>1</sup> [38, ch. 9] has a typing rule for lambda expression and application as follows:

$$\frac{\Gamma, x : \tau_1 \vdash e : \tau_2}{\Gamma \vdash \lambda x. e : \tau_1 \rightarrow \tau_2} \quad \frac{\Gamma \vdash e_1 : \tau_1 \rightarrow \tau_2 \quad \Gamma \vdash e_2 : \tau_1}{\Gamma \vdash e_1(e_2) : \tau_2}$$

Meaning,  $\lambda x. e$  has type  $\tau_1 \rightarrow \tau_2$  if  $e$  has type  $\tau_2$  under the extended context additionally assuming that  $x$  has type  $\tau_1$ . And,  $e_1(e_2)$  has type  $\tau_2$  if  $e_1$  is a function of type  $\tau_1 \rightarrow \tau_2$  and it's argument  $e_2$  has type  $\tau_1$ .

## Product & Labelled Sum Types

Briefly demonstrate. Link to TAPL *Variants* and products

## Dynamic Type Systems

*Dynamic Typing* has purported strengths allowing rapid development and flexibility, evidenced by their popularity [33, 6]. Of particular relevance to this project, execution traces are known to help provide insight to errors [29], yet statically typed languages remove the ability to execute programs with type errors, whereas dynamically typed languages do not.

A *dynamically typed system* can be implemented and represented semantically by use of *dynamic type tags* and a *dynamic type*<sup>2</sup> [50]. Then, runtime values can have their type checked at runtime and *cast* between types. This suggests a way to encode dynamic typing via *first-class*<sup>3</sup> cast expressions which maintain and enforce runtime type constraints alongside a dynamic type written `?`.

---

<sup>1</sup>Simply typed lambda calculus.

<sup>2</sup>Not necessarily needed for implementation, but is useful when reasoning about dynamic types within a formal type system or when considering types within a *static* context.

<sup>3</sup>Directly represented in the language syntax as expressions.

Cast expressions can be represented in the syntax of expression by  $e\langle\tau_1\Rightarrow\tau_2\rangle$  for expression  $e$  and types  $\tau_1, \tau_2$ , encoding that  $e$  has type  $\tau_1$  and is cast to new type  $\tau_2$ . An intuitive way to think about these is to consider two classes of casts:

- *Injections* – Casts *to* the dynamic type  $e\langle\tau\Rightarrow?\rangle$ . These are effectively equivalent to type tags, they say that  $e$  has type  $\tau$  but that it should be treat dynamically.
- *Projections* – Casts *from* the dynamic type  $e\langle?\Rightarrow\tau\rangle$ . These are type requirements, for example the add operator could require inputs to be of type `int`, and such a projection would force any dynamic value input to be cast to `int`.

Then when *injections* meet *projections* meet,  $v\langle\tau_1\Rightarrow?\Rightarrow\tau_2\rangle$ , representing an attempt to perform a cast  $\langle\tau_1\Rightarrow\tau_2\rangle$  on  $v$ . We check the cast is valid and perform if so:

$$\frac{\tau_1 \text{ is castable to } \tau_2}{v\langle\tau_1\Rightarrow?\Rightarrow\tau_2\rangle \mapsto v'} \qquad \frac{\tau_1 \text{ is \textcolor{red}{not} castable to } \tau_2}{v\langle\tau_1\Rightarrow?\Rightarrow\tau_2\rangle \mapsto v\langle\tau_1\Rightarrow?\Rightarrow\tau_2\rangle}$$

Compound type casts can be broken down during evaluation upon usage of such constructs. For example, applying  $v$  to a *wrapped*<sup>4</sup> functions could decompose the cast to separately cast the applied argument and then the result. Inspired by, *semantic casts* [36] in *contract* systems [37]:

$$(f\langle\tau_1 \rightarrow \tau_2\Rightarrow\tau'_1 \rightarrow \tau'_2\rangle)(v) \mapsto (f(v\langle\tau'_1\Rightarrow\tau_1\rangle)\langle\tau_2\Rightarrow\tau'_2\rangle)$$

Or if  $f$  has the dynamic type:

$$(f\langle?\Rightarrow\tau'_1 \rightarrow \tau'_2\rangle)(v) \mapsto (f(v\langle\tau'_1\Rightarrow?\rangle)\langle?\Rightarrow\tau'_2\rangle)$$

Then direction of the casts reflects the *contravariance* [49, ch. 2] of functions<sup>5</sup> in their argument. See that the cast  $\langle\tau'_1\Rightarrow\tau_1\rangle$  on the argument is *reversed* with respect to the original cast on  $f$ . This makes sense as we must first cast the applied input to match the actual input type of the function  $f$ .

Hence, casts around functions (type information) will be moved to the actual arguments at runtime, meeting with casts casts on the argument, resulting in a cast error or a successful casts.

## Gradual Type Systems

A *gradual type system* [21, 34] combines static and dynamic typing. Terms may be annotated as dynamic, marking regions of code omitted from type-checking but still *interoperable* with static code. For example, the following type checks:

```
let x : ? = 10; // Dynamically typed
x ++ "str"      // Statically typed
```

Where `++` is string concatenation expecting inputs to be `++ "str"`. But would then cause a runtime *cast error* when attempting to calculate `10 ++ "str"`.

It does this by representing casts as expressed previously. The language is split into two parts:

<sup>4</sup>Wrapped in a cast between function types.

<sup>5</sup>A bifunctor.

- The *external language* – where static type checking is performed which allows annotating expressions with the dynamic type.
- The *internal language* – where evaluation and runtime type checking is performed via cast expressions.<sup>6</sup> The example above would reduce to a *cast error*<sup>7</sup>:

`10<int=>?> ++ "str" > ++ "str"`

For type checking, a *consistency* relation  $\tau_1 \sim \tau_2$  is introduced meaning *types*  $\tau_1, \tau_2$  are *consistent*. This is a weakening of the type equality requirements in normal static type checking, allowing consistent types to be used additionally.

Consistency must satisfy a few properties: that the dynamic type is consistent with every type,  $\tau \sim ?$  for all types  $\tau$ , that  $\sim$  is reflexive and symmetric, and two concrete types<sup>8</sup> are consistent iff they are equal<sup>9</sup>. A typical definition would be like:

$$\frac{}{\tau \sim ?} \quad \frac{}{\tau \sim \tau} \quad \frac{\tau_1 \sim \tau_2}{\tau_2 \sim \tau_1} \quad \frac{\tau_1 \sim \tau'_1 \quad \tau_2 \sim \tau_2}{\tau_1 \rightarrow \tau_2 \sim \tau'_1 \rightarrow \tau'_2}$$

This is very similar to the notion of *subtyping* [38, ch. 15] with a *top* type  $\top$ , but with symmetry instead of transitivity.

Then typing rules can be written to use consistency instead of equality. For example, application typing:

$$\frac{\Gamma \vdash e_1 : \tau_1 \quad \Gamma \vdash e_2 : \tau'_2 \quad \tau_1 \blacktriangleright \rightarrow \tau_2 \rightarrow \tau \quad \tau_2 \sim \tau'_2}{\Gamma \vdash e_1(e_2) : \tau'_2}$$

Where  $\blacktriangleright \rightarrow$  is a pattern matching function to extract the argument and return types from a function type.<sup>10</sup> Intuitively,  $e_1(e_2)$  has type  $\tau'_2$  if  $e_1$  has type  $\tau'_1 \rightarrow \tau'_2$  or  $?$  and  $e_2$  has type  $\tau_1$  which is consistent with  $\tau'_1$  and hence is assumed that it can be passed into the function.

But, for evaluation to work the static type information needs to be encoded into casts to be used in the dynamic internal language, for which the evaluation semantics are defined. This is done via *elaboration*, similarly to Harper and Stone's approach to defining (globally inferred) Standard ML [42] by elaboration to an explicitly typed internal language XML [48]. The *elaboration judgement*  $\Gamma \vdash e \rightsquigarrow e' : \tau$  read as: external expression  $e$  is elaborated to internal expression  $d$  with type  $\tau$  under typing context  $\Gamma$ . For example we need to insert casts around function applications:

$$\frac{\Gamma \vdash e_1 \rightsquigarrow d_1 : \tau_1 \quad \Gamma \vdash e_2 \rightsquigarrow d_2 : \tau'_2 \quad \tau_1 \blacktriangleright \rightarrow \tau_2 \rightarrow \tau \quad \tau_2 \sim \tau'_2}{\Gamma \vdash e_1(e_2) : \tau \rightsquigarrow (d_1 \langle \tau_1 \Rightarrow \tau_2 \rightarrow \tau \rangle) (d_2 \langle \tau'_2 \Rightarrow \tau_2 \rangle) : \tau}$$

If,  $e_1$  elaborates to  $d_1$  with type  $\tau_1 \sim \tau_2 \rightarrow \tau$  and  $e_2$  elaborates to  $\tau'_2$  with  $\tau_2 \sim \tau_2$  then we place a cast<sup>11</sup> on the function  $d_1$  to  $\tau_2 \rightarrow \tau$  and on the argument  $d_2$  to the function's expected

<sup>6</sup>i.e. the proposed *dynamic type system* above.

<sup>7</sup>Cast errors now represented with a strike-through and in red. From here-on they are considered as first-class constructs.

<sup>8</sup>No sub-parts are dynamic.

<sup>9</sup>e.g.  $\tau_1 \rightarrow \tau_2 \sim \tau'_1 \rightarrow \tau'_2$  iff  $\tau_1 = \tau'_1$  and  $\tau_2 = \tau'_2$  when  $\tau_1, \tau'_1, \tau_2, \tau'_2$  don't contain  $?$ .

<sup>10</sup>This makes explicit the implicit pattern matching used normally.

<sup>11</sup>This cast is required, as if  $\tau_1 = ?$  then we need a cast to realise that it is even a function. Otherwise  $\tau_1 = \tau_2 \rightarrow \tau$  and the cast is redundant.

argument type  $\tau_2$  to perform runtime type checking of arguments. Intuitively, casts must be inserted whenever type consistency is used, though the casts to insert are non-trivial [18].

The runtime semantics of the internal expression is that of the *dynamic type system* discussed above (2.1.1). A cast is determined to succeed iff the types are *consistent*.

The *refined criteria* for gradual typing [21] also provides an additional property for such systems to satisfy, the *gradual guarantee*, formalising the intuition that adding and removing annotations should *not* change the *behaviour* of the program except for catching errors either dynamically or statically.

## Bidirectional Type Systems

A *bidirectional type system* [22] takes on a more algorithmic definition of typing judgements, being more intuitive to implement. They also allow some amount of local type inference [43], allowing programmers to omit *type annotations*, instead type information. Global type inference systems [38, ch. 22] can be *difficult to implement*, often via constraint solving [7, ch. 10], and difficult or impossible to *balance* with complex language features, for example global inference in System F (2.1.1) is undecidable [45].

This is done in a similar way to annotating logic programming [56, p. 123], by specifying the *mode* of the type parameter in a typing judgement, distinguishing when it is an *input* (type checking) and when it is an *output* (type synthesis).

We express this with two judgements:

$$\Gamma \vdash e \Rightarrow \tau$$

Read as: *e synthesises a type  $\tau$  under typing context  $\Gamma$ . Type  $\tau$  is an output.*

$$\Gamma \vdash e \Leftarrow \tau$$

Read as: *e analyses against a type  $\tau$  under typing context  $\Gamma$ . Type  $\tau$  is an input*

When designing such a system care must be taken to ensure *mode correctness* [54]. Mode correctness ensures that input-output dataflow is consistent such that an input never needs to be *guessed*. For example the following function application rule is *not* mode correct:

$$\frac{\Gamma \vdash e_1 \Leftarrow \tau_1 \rightarrow \tau_2 \quad \Gamma \vdash e_2 \Leftarrow \tau_1}{\Gamma \vdash e_1(e_2) \Leftarrow \tau_2}$$

We try to *check*  $e_2$  with input  $\tau_1$ <sup>12</sup> which is *not known* from either an *output* of any premise nor from the *input* to the conclusion,  $\tau_2$ . On the other hand, the following *is* mode correct:

$$\frac{\Gamma \vdash e_1 \Rightarrow \tau_1 \rightarrow \tau_2 \quad \Gamma \vdash e_2 \Leftarrow \tau_1}{\Gamma \vdash e_1(e_2) \Leftarrow \tau_2}$$

Where  $\tau_1$  is now known, being *synthesised* from the premise  $\Gamma \vdash e_1 \Rightarrow \tau_1 \rightarrow \tau_2$ . As before,  $\tau_2$  is known as it is an input in the conclusion  $\Gamma \vdash e_1(e_2) \Leftarrow \tau_2$ .

Such languages will typically have three obvious rules. First, we should have that variables can synthesise their type, after all it is accessible from the typing context  $\Gamma$ :

$$\text{Var} \frac{x : \tau \in \Gamma}{\Gamma \vdash x \Rightarrow \tau}$$

---

<sup>12</sup>Highlighted in red as an error.

And annotated terms can synthesise their type by just looking at the annotation  $e : \tau$  and checking the annotation is valid:

$$\text{Annot} \frac{\Gamma \vdash e \Leftarrow \tau}{\Gamma \vdash e : \tau \Rightarrow \tau}$$

Finally, when we check against a type that we can synthesise a type for, variables for example. It would make sense to be able to *check*  $e$  against this same type  $\tau$ ; we can synthesise it, so must be able to check it. This leads to the subsumption rule:

$$\text{Subsumption} \frac{\Gamma \vdash e \Rightarrow \tau' \quad \tau = \tau'}{\Gamma \vdash e \Leftarrow \tau}$$

## Contextual Modal Type Theory

Not *hugely* relevant really...

## System F

*Very brief explanation with less/no maths*

## Recursive Types

*Very brief explanation with less/no maths*

### 2.1.2 The Hazel Calculus

Hazel is a language that allows the writing of incomplete programs, evaluating them, and evaluating around static & dynamic errors.<sup>13</sup>

It does this via adding *expression holes*, which can both be typed and have evaluation proceed around them seamlessly. This allows the evaluation around errors by placing them in holes.

The core calculus [15] is a gradually and bidirectionally typed lambda calculus. Therefore it has a locally inferred bidirectional *external language* with the dynamic type  $?$  elaborated to an explicitly typed *internal language* including cast expressions.

The full semantics are documented in the Hazel Formal Semantics appendix A, but only rules relevant to addition of *holes* are discussed in this section. The combination of gradual and bidirectional typing system is itself non-trivial, but only particularly notable consequences are mentioned here. The intuition should be clear from the previous gradual and bidirectional typing sections.<sup>14</sup>

## Syntax

The syntax, in Fig. 2.1, consists of *types*  $\tau$  including the dynamic type  $?$ , *external expressions*  $e$  including (optional) annotations, *internal expressions*  $d$  including cast expressions. The external language is *bidirectionally typed*, and therefore is a locally inferred surface syntax for the language, and is statically elaborated to (explicitly typed) *internal expressions*.

<sup>13</sup>Among other features, like an structure editor with syntactically meaningless states, and various learning aids.

<sup>14</sup>The difficulties combining gradual and bidirectional typing are largely orthogonal to adding holes.

Notating  $\langle\!\rangle^u$  or  $\langle\!e\!\rangle^u$  for empty and non-empty holes respectively, where  $u$  is the *metavariable* or name for a hole. Internal expression holes,  $\langle\!\rangle_\sigma^u$  or  $\langle\!e\!\rangle_\sigma^u$ , also maintain an environment  $\sigma$  mapping variables  $x$  to internal expressions  $d$ . These internal holes act as *closures*, recording which variables have been substituted during evaluation.<sup>15</sup>

$$\begin{aligned}\tau &::= b \mid \tau \rightarrow \tau \mid ? \\ e &::= c \mid x \mid \lambda x : \tau. e \mid \lambda x. e \mid e(e) \mid \langle\!\rangle^u \mid \langle\!e\!\rangle^u \mid e : \tau \\ d &::= c \mid x \mid \lambda x : \tau d \mid d(d) \mid \langle\!\rangle_\sigma^u \mid \langle\!d\!\rangle_\sigma^u \mid d\langle\tau \Rightarrow \tau\rangle \mid d\langle\tau \Rightarrow ? \Rightarrow \tau\rangle\end{aligned}$$

**Figure 2.1:** Syntax: *types*  $\tau$ , *external expressions*  $e$ , *internal expressions*  $d$ . With  $x$  ranging over variables,  $u$  over hole names,  $\sigma$  over  $x \rightarrow d$  *internal language* substitutions/environments,  $b$  over base types and  $c$  over constants.

## External Language

We have a bidirectionally static semantics for the *external language*, giving the bidirectional typing judgements:  $\Gamma \vdash e \Rightarrow \tau$  and  $\Gamma \vdash e \Leftarrow \tau$ . Holes synthesise the *dynamic type*, a natural choice made possible by the use of gradual types:

$$\text{SNEHole} \frac{\Gamma \vdash e \Rightarrow \tau}{\Gamma \vdash \langle\!e\!\rangle^u \Rightarrow ?} \quad \text{SEHole} \frac{}{\Gamma \vdash \langle\!\rangle^u \Rightarrow ?}$$

One notable consequence of combining gradual and bidirectional typing is that the *subsumption rule* in bidirectional typing is naturally extended to allow subsuming any terms of *consistent* types:

$$\text{ASubsume} \frac{\Gamma \vdash e \Rightarrow \tau' \quad \tau \sim \tau'}{\Gamma \vdash e \Leftarrow \tau}$$

Of course  $e$  should type check against  $\tau$  if it can synthesise a consistent type as the goal of type consistency is that we may type check terms as if they were of the consistent type.

The remaining rules are detailed in Fig. A.2, with *consistency* relation  $\sim$  in Fig. A.3 and (fun) type matching relation,  $\blacktriangleright \rightarrow$  in Fig. A.4.

## Internal Language

The internal language is non-bidirectionally typed and requires an extra *hole context*  $\Delta$  mapping each hole *metavariables*  $u$  to it's *checked type*  $\tau$ <sup>16</sup> and the type context  $\Gamma$  under which the hole was typed. Each metavariable context notated as  $u :: \tau[\Gamma]$ , notation borrowed from contextual modal type theory (CMTT) [32].<sup>17</sup>

The type assignment judgement  $\Delta; \Gamma \vdash d : \tau$  means that  $d$  has type  $\tau$  under typing and hole contexts  $\Gamma, \Delta$ . The rules for holes take their types from the hole context and ensure that

<sup>15</sup>This is required, as holes may later be substituted, with variables then receiving their values from the closure environment.

<sup>16</sup>Originally required when typing the external language expression. See Elaboration section.

<sup>17</sup>Hole contexts corresponding to *modal contexts*, hole names with *metavariables*, and holes with *metavariable closures* (on environments  $\sigma$ ).

the hole environment substitutions  $\sigma$  are well-typed<sup>18</sup>:

$$\text{TAEHole} \frac{u :: \tau[\Gamma'] \in \Delta \quad \Delta; \Gamma \vdash \sigma : \Gamma'}{\Delta; \Gamma \vdash \llbracket u \rrbracket_{\sigma}^u : \tau}$$

Hazel is proven to preserve typing; a well-typed external expression will elaborate to a well-typed internal expression which is consistent to the external type. Hence, there is no need for an algorithmic definition of the internal language typing.

Full rules in Fig. A.6. Formally speaking these define categorical judgements [40]. Additionally, ground types and a matching function are defined in Figs. A.8 & A.11, and typing of hole environments/substitution in Fig. A.7

## Elaboration

Cast insertion requires an elaboration to the *internal language*, so must output an additional context for holes  $\Delta$ . The judgements are notated:

$$\Gamma \vdash e \Rightarrow \tau \rightsquigarrow d \dashv \Delta$$

*external expression  $e$  which synthesises type  $\tau$  under type context  $\Gamma$  is elaborated to internal expression  $d$  producing hole context  $\Delta$ .*

$$\Gamma \vdash e \Leftarrow \tau \rightsquigarrow d : \tau' \dashv \Delta$$

*external expression  $e$  which type checks against type  $\tau$  under type context  $\Gamma$  is elaborated to internal expression  $d$  of consistent type  $\tau'$  producing hole context  $\Delta$ .*

The elaboration judgements for holes must add the hole to the output hole context. And they will elaborate to holes with the default empty environment  $\sigma = \text{mathrm{id}}(\Gamma)$ , i.e. no substitutions.

$$\begin{array}{c} \text{ESEHole} \frac{}{\Gamma \vdash \llbracket u \rrbracket^u \Rightarrow ? \rightsquigarrow \llbracket u \rrbracket_{\text{id}(\Gamma)}^u \dashv u :: \llbracket \Gamma \rrbracket} \\ \text{EAESHole} \frac{}{\Gamma \vdash \llbracket u \rrbracket^u \Leftarrow \tau \rightsquigarrow \llbracket u \rrbracket_{\text{id}(\Gamma)}^u : \tau \dashv u :: \tau[\Gamma]} \end{array}$$

When elaborating a *type checked* hole, this checked type is used. Typing them instead as  $?$  would imply type information being lost.<sup>19</sup>

The remaining elaboration rules are stated in Fig. A.5.

## Final Forms

The primary addition of Hazel is the addition of a new kind of *final forms* and *values*. This is what allows evaluation to proceed around holes and errors. There are three types of final forms:

- *Values* – Constants and functions.
- *Boxed Values* – Values wrapped in *injection* casts, or *function*<sup>20</sup> casts.

<sup>18</sup>With respect to the original typing context captured by the hole.

<sup>19</sup>Potentially leading to incorrect cast insertion.

<sup>20</sup>Between function types

- *Indeterminate Final Forms* – Terms containing holes that cannot be directly evaluated, e.g. holes or function applications where the function is indeterminate, e.g.  $\llbracket \cdot \rrbracket^u(1)$ .

Importantly, *any* final form can be treated as a value (in a *call-by-value* context). For example, they can be passed inside a (determinate) function:  $(\lambda x.x)(\llbracket \cdot \rrbracket^u)$  can evaluate to  $\llbracket \cdot \rrbracket^u$ .

Full rules are present in Fig. A.9.

## Dynamics

A small-step contextual dynamics [19, ch. 5] is defined on the internal expressions to define a *call-by-value*<sup>21</sup> **ENSURE THIS** evaluation order.

Like the *refined criteria* [21], Hazel presents a rather different cast semantics designed around *ground types*, that is *base types*<sup>22</sup> and least specific<sup>23</sup> compound types associated via a ground matching relation mapping compound types to their corresponding ground type, e.g.  $\text{int} \rightarrow \text{int} \triangleright_{\text{ground}} ? \rightarrow ?$ . This formalisation more closely represents common dynamically typed language implementations which only use generic type tags like *fun*, corresponding to the ground type  $? \rightarrow ?$ . However, the idea of type consistency checking when *injections* meet *projections* remains the same.<sup>24</sup>

The cast calculus is more complex as discussed previously, due to being based around *ground types*. However, the fundamental logic is similar to the dynamic type system described previously in section 2.1.1.

Evaluation proceeds by *capture avoiding variable substitution*  $[d'/x]d$  (substitute  $d'$  for  $x$  in  $d$ ). Additionally, substitutions are recorded in each hole's environment  $\sigma$  by substituting all occurrences of  $x$  for  $d$  in each  $\sigma$  **Add figure for this**.

The instruction transitions are in Fig. A.10 and the contextual dynamics defining a small-step semantics in A.12. **SWAP DYNAMICS BACK TO DETERMINISTIC**

A contextual dynamics is defined via an Evaluation context... (*TODO, explain evaluation contexts as will be relevant to the Stepper EV\_MODE explanation*)

## Hole Substitutions

Holes are indexed by *metavariables*  $u$ , and can hence also be substituted. Hole substitution is a *meta* action  $\llbracket d/u \rrbracket d'$  meaning substituting each hole named  $u$  for expression  $d$  in some term  $d'$  with the holes environment. Importantly, the substitutions  $d$  can contain variables, whose values are found by checking the holes *environment*, effectively making a *delayed substitution*. See the following rule:

$$\llbracket d/u \rrbracket \llbracket \cdot \rrbracket_\sigma^u = \llbracket d/u \rrbracket \sigma d$$

When substituting a matching hole  $u$ , we replace it with  $d$  and *apply substitutions from the environment  $\sigma$  of  $u$  to  $d$* .<sup>25</sup> This corresponds to *contextual substitution* in CMTT. The remaining rules can be found in A.13

This can be thought of as a *fill-and-resume* functionality, allowing incomplete program parts to be filled *during evaluation* rather than only before evaluation.

<sup>21</sup>Values in this sense are *final forms*.

<sup>22</sup>Like `int` or `bool`.

<sup>23</sup>In the sense that  $?$  is more general than any concrete type.

<sup>24</sup>With projections/injections now being to/fro *ground types*.

<sup>25</sup>After first substituting any occurrences of  $u$  in the environment  $\sigma$

As Hazel is a *pure language*<sup>26</sup> and as holes act as closures, then performing hole substitution is *commutative* with respect to evaluation. That is, filling incomplete parts of a program *before* evaluation gives the same result as filling *after* evaluation then resuming evaluation. Formalised in **ref theorems**.

### 2.1.3 The Hazel Implementation

The Hazel implementation [2] is written primarily in ReasonML and OCaml with approx. 65,000 lines of code. It implements the Hazel core calculus along with many additional features. Relevant features and important abstractions are discussed here.

**Discuss why the main branch was chosen over THI, hole substitution one etc. (main point being better documentation, sum types, though still very lacking**

#### Language Features

- Lists –
- Tuples –
- Labelled Sums –
- Type Aliases –
- Pattern Matching –
- Explicit Polymorphism – System F style
- Recursive Types –

#### Monadic Evaluator

**This is extremely hard to explain concisely!! or at all... Ask on Slack?**

**Move most of this to implementation, give vague description/motivation and emphasise it's complexity**

The transition semantics are defined on an intricate *monadic* **this is actually a monad...?** evaluator which is discussed in depth in the Implementation section **REF**. It is equipped with custom `let.` and `and.` binding operators<sup>27</sup> [8], and a `otherwise` and `req_final` function. Allowing transition rules to be simply written (simplified):

```
...
| Seq(d1, d2) =>
  let. _ = otherwise(d1 => Seq(d1, d2))
  and. d1' =
    req_final(req(state, env), d1 => Seq1(d1, d2), d1);
  Step({expr: d2, state});
...
| Int(i) =>
  let. _ = otherwise(env, Int(i));
  Value;
```

---

<sup>26</sup>Having no side effects.

<sup>27</sup>Which allow a convenient for writing code with binding functions.

```

...
| EmptyHole =>
  let. _ = otherwise(env, EmptyHole);
  Indet;
...

```

Representing rules by a `let. _ = otherwise(env, r)` determining how to rewrap an expression if it is unevaluable. A term may be unevaluable if it requires some subterms to be *final*, but that this is not the case.

The `req_final(req(state, env), _, d)` function will pass a reference the recursive evaluation abstraction `req`, which the abstraction may choose to recursively evaluate, and bind a resulting value for use in calculating the next step.

**Explain the middle `EvalCtx` arg to `req_final`...**

Each transition returns either a possible step `Step({expr})`, or states that the term is indeterminate `Indet`, or a value `Value`.<sup>28</sup>

The results that these ‘evaluate’ to are abstract, they do not necessarily have to be terms, as demonstrated by the following implementations:

- **Final Form Checker** – Returns whether a term is one of each of the final form. Using the evaluator abstraction with this means there is no need to maintain a separate syntactic value checker, instead it is derived directly from the evaluation transitions. Yet, it is still syntactic since the abstraction does not actually perform evaluation steps and continue evaluation, instead it just makes the step accessible<sup>29</sup> to the implementation.
- **Evaluator** – Maintains a stack machine and actually performs the reduction steps.
- **Stepper** – Returns a list of possible evaluation steps in terms of *evaluation contexts* under a non-deterministic evaluation method **Explain how `EvalCtx.t => EvalCtx.t` in `req_final` allows this**. The evaluation order can then be user-controlled.

Each evaluation method module is transformed into an evaluator module by being passed into an OCaml *functor*. The resulting module produces a `transition` method that takes terms to evaluation results in an environment<sup>30</sup>.

## UI Architecture

Model View Update model.

### 2.1.4 Bounded Non-Determinism

The search procedure [20] is effectively a *dynamic type-directed* test generator, attempting to find dynamic type errors. In Hazel, dynamic type errors will manifest themselves as *cast errors*.

Type-directed generation of inputs and searching for one which manifests an error is a *non-deterministic* algorithm [57].

<sup>28</sup>Or a constructor, discussed more in the Implementation section.

<sup>29</sup>And the final form checker will just classify such an expression immediately as non-final.

<sup>30</sup>Mapping variable bindings.

## High Level

Non-determinism can be declaratively represented by two ideas:

- *Choice* (*|||*): Determines the search space, flipping a coin will return heads *or* tails.
- *Failure* (*fail*): The *empty* result, no solutions to the algorithm.

Suppose the result of the algorithm has type  $\tau$ . These can be represented by operations:

$$||| : \tau \rightarrow \tau \rightarrow \tau$$

$$\text{fail} : \tau$$

Where *|||* should be *associative* and *fail* should be a *zero element*, forming a *monoid*:

$$x ||| (y ||| z) = (x ||| y) ||| z \quad \text{fail} ||| x = x = x ||| \text{fail}$$

That is, the order of making binary choices does not matter, and there is no reason to choose failure.

There are many proposed ways to manage programs with choice:

**Logic Programming:** Languages like Prolog (**cite**) and Curry (**cite**) express non-determinism by directly implementing *choice* with non-deterministic evaluation. Prolog searches via back-tracking, while Curry abstracts the search procedure.

There are ways to embed this within OCaml. Inspired by Curry, Kiselyov [14] created a tagless final style [27] domain specific language within OCaml. This fully abstracts the search procedure from the non-deterministic algorithm definition.

## Continuations:

**Effect Handlers:** Effect handlers allow the description of effects and factors out the handling of those effects. Non-determinism can be represented by an effect consisting of the choice and fail operators [4, 23], while handlers can flexibly define the search procedure and accounting logic, e.g. storing solutions in a list.

In order to enumerate try multiple solutions, *multiple continuations* must be used. JSOO<sup>31</sup> does not (at time of writing) allow these.

**Monadic:** The non-determinism effect can be expressed as a monad. A monad is a parametric type  $m(\alpha)$  equipped with two operations, **return** and **bind**, where **bind** is associative and **return** acts as an identity with respect to **bind**: A monad can then be extended to represent nondeterminism by adding a **choice** and **fail** operator satisfying the usual laws:

$$\text{choice} : \forall \alpha. m(\alpha) \rightarrow m(\alpha) \rightarrow m(\alpha)$$

$$\text{fail} : \forall \alpha. m(\alpha)$$

Where **bind** distributes over **choice**, and **fail** is a left-identity for **bind**.

$$\text{bind}(m_1 ||| m_2)(f) = \text{bind}(m_1)(f) ||| \text{bind}(m_2)(f)$$

---

<sup>31</sup> Javascript of OCaml. A dependency of Hazel.

A monad  $m$ , is a parameterised type with operations:

$$\text{bind} : \forall \alpha, \beta. m(\alpha) \rightarrow (a \rightarrow m(\beta)) \rightarrow m(\beta)$$

$$\text{return} : \forall \alpha. a \rightarrow m(\alpha)$$

Satisfying the monad laws:

$$\text{bind}(\text{return}(x))(f) = f(x)$$

$$\text{bind}(m)(\text{return}) = m$$

$$\text{bind}(\text{bind}(m)(f))(g) = \text{bind}(m)(\text{fun } x \rightarrow \text{bind}(f(x))(g))$$

**Figure 2.2:** Monad Definition

$$\text{bind}(\text{fail})(f) = \text{fail}$$

In this context, `bind` takes a non-deterministic choice and a function which maps each *guess* in the state space to another choice, returning this choice of all the possible resulting choices after applying the function to the possible input choices. See how distributivity represents this interpretation. `fail` being the left identity of `bind` states that you cannot make any guesses from the no choice (`fail`). If a potential guess does not solve the problem, then just return `fail` (hence the name). For example:

**Figure 2.3:** Non-determinism Monad Example

While the `bind` and `return` operators are *not* required to represent non-determinism, they are a *familiar*<sup>32</sup> way to represent a large class of effects in general way.

## Low Level

Which may abstract over different search/backtracking procedures. Writing these directly can be complex, unintuitive, and require much code, but is very flexible. (**cite evidence/reasoning**):

**Depth First Search:** Generate options where choice is possible, and backtrack once each option has been fully tested.

**Breadth First Search:**

**Iterative Deepening:**

## 2.2 Starting Point

### Concepts

The foundations of most concepts in understanding Hazel from Part IB Semantics of Programming (and Part II Types later). The concept of gradual typing briefly appeared in Part IB

---

<sup>32</sup>For OCaml developers and functional programmers.

Concepts of Programming Languages, but was not formalised. Dynamic typing, gradual typing, holes, and contextual modal type theory were not covered in Part IB, so were partially researched leading up to the project, then researched further in greater depth during the early stages. Similarly, Part IB Artificial Intelligence provided some context for search procedures. Primarily, the OCaml search procedure for ill-typed witnesses Seidel et al. [20] and the Hazel core language [15] were researched over the preceding summer.

### **Tools and Source Code**

My only experience in OCaml was from the Part IA Foundations of Computer Science course. The Hazel source code had not been inspected in any detail until after starting the project.

## **2.3 Requirement Analysis**

## **2.4 Software Engineering Methodology**

Do the theory first.

Git. Merging from dev frequently (many of which were very difficult, as my code touches all of type checking and much of dynamics; and some massive changes, i.e. UI update).

Talking with devs over slack.

Using existing unit tests & tests in web documentation to ensure typing is not broken.

## **2.5 Legality**

MIT licence for Hazel.

# Chapter 3

## Implementation

This project was conducted in *two* major phases:

First, I constructed a core mathematical theory for *type slicing* and *cast slicing* formalising what these ideas actually were and considered the changes to the system presented by Seidel et al. for the *type error witnesses search procedure* to work in Hazel.

Then, I implemented the theories, making it suitable for implementation and extending it to the majority of the Hazel language. Further, suitable deviations from the theory were made upon critical evaluation and are detailed throughout.

**Annotate the above with the relevant section links!**

**Motivate and pose questions for type slicing and cast slicing.**

### 3.1 Type Slicing Theory

**Might be worth deferring even more mathematical definitions to the appendices in favour shorter worded definitions in this section**

**Replace all occurrences of ‘typing context’ with ‘typing assumptions’ to avoid name clash with expression/program contexts.**

I develop a novel method I term *type slicing* as a mechanism to aid programmers in understanding *why* a term has a given type via static means. Three slicing mechanism have been devised with differing characteristics, all of which associate terms with their typing derivation to produce a *typing slices*.

The first two criteria attempt to give insight on the structure of the typing derivations, and hence how types are decided. While the third criterion gives a complete picture of the regions of code which contribute to the a term’s type.

I would like to stress that the second and third criterion were *very challenging* to formalise, requiring extensive mathematical machinery: *context slices* (section 3.1.2), *type flows* (ref appendix), *checking context* (definition 3), *type-indexed slices* (section 3.1.3).

**Clarify on and ensure terminology is consistent (typing vs checking/analysis vs synthesis)**

**Make some brief arguments into why the first two criteria are still useful.**

**PLACE ALL IMPORTANT DEFINITIONS INSIDE DEFINITION ENVIRONMENTS**

### 3.1.1 Expression Typing slices

A *expression typing slice*  $\rho$ , is a pair  $\varsigma^\gamma$ , consisting of an *expression slice*  $\varsigma$  and *typing context slice*  $\gamma$  which are calculated based on some typing *criterion*<sup>1</sup> based on the typability of the slice  $\varsigma$  under context  $\gamma$ .

Intuitively, an expression slice is a Hazel external expression highlighting the sub-terms of relevance to the *typing criterion*. For example if my criterion is to *omit terms which are typed as Int*, then the following expressions highlights as:

$$(\lambda x : \text{Int}. \lambda y : \text{Bool}. x)(1)$$

Formally, I represent this by specifying which sub-terms are omitted in the highlighted expression. So, Replace each omitted sub-term with a *gap*, notated  $\square$ . This is the same definition of a slice as presented in [28].<sup>2</sup> i.e. representing the above highlighting we get slice:

$$(\lambda x : \text{Int}. \lambda y : \text{Bool}. \square)(\square)$$

Additionally, it is useful to omit variable names. For this I introduce *patterns*  $p$  for variable bindings:

$$p ::= \square \mid x$$

This gives the following extended syntax of expression slices,  $\varsigma$ , extending fig. 2.1:

$$\varsigma ::= \square \mid c \mid x \mid \lambda p : v. \varsigma \mid \lambda x. \varsigma \mid \varsigma(\varsigma) \mid \llbracket \varsigma \rrbracket^u \mid \llbracket \varsigma \rrbracket^u \mid \varsigma : v$$

Where  $v$  are types, similarly with potential omitted sub-term gaps:

$$v ::= \square \mid ? \mid b \mid v \rightarrow v$$

These slices are then allowed to be *typed* by representing gaps  $\square$  by holes of fresh metavariables  $\llbracket \cdot \rrbracket^u$  in *expressions*, fresh variables in *patterns*, and the dynamic type in *types*, see (fig APPENDIX). From here-on consider  $\square$  as interchangeable with a hole  $\llbracket \cdot \rrbracket^u$  of fresh metavariable  $u$  or the dynamic type.

We then have a *precision* relation on expression slices,  $\varsigma_1 \sqsubseteq \varsigma_2$  meaning  $\varsigma_1$  is less or equally precise than  $\varsigma_2$ , that is  $\varsigma_1$  matches  $\varsigma_2$  structurally except that some subterms may be gaps, see **ref appendix**. For example, see this precision chain:

$$\square \sqsubseteq \square + \square \sqsubseteq 1 + \square \sqsubseteq 1 + 2$$

We have that  $\sqsubseteq$  is a partial order (**cite**), that is, satisfies reflexivity, antisymmetry, and transitivity. Respectively:

$$\frac{}{\varsigma \sqsubseteq \varsigma} \quad \frac{\varsigma_1 \sqsubseteq \varsigma_2 \quad \varsigma_2 \sqsubseteq \varsigma_1}{\varsigma_1 = \varsigma_2} \quad \frac{\varsigma_1 \sqsubseteq \varsigma_2 \quad \varsigma_2 \sqsubseteq \varsigma_3}{\varsigma_1 \sqsubseteq \varsigma_3}$$

We also have a *bottom* (least) element,  $\square \sqsubseteq \varsigma$  (for all  $\varsigma$ ). This relation is trivially extended to include complete expressions  $e$  which satisfy that: if  $e \sqsubseteq \varsigma$  then  $e = \varsigma$ , i.e. complete terms are always upper bounds of precision chains.

An expression slice  $\varsigma$  of  $e$  is a slice such that  $e \sqsubseteq \varsigma$ .

<sup>1</sup>One of the three slicing mechanisms.

<sup>2</sup>With their ‘holes’ equating with my ‘gaps’. Different terminology used to distinguish with Hazel’s holes

*Typing context slices* are simply a typing context  $\Gamma$ , which is used to represent the notion of *relevant typing assumption*. Typing contexts are just functions mapping variables to types notated  $x : \tau$  (see section 2.1.1). Functions are sets, so they also have a partial order of subset inclusion,  $\subseteq$ . Again, we have a bottom element,  $\emptyset$ . These are notated  $\gamma$  and if  $\gamma \subseteq \Gamma$  then  $\gamma$  is a slice of  $\Gamma$ .

The precision relation and subset inclusion can be extended pointwise to give a partial order,  $\sqsubseteq$ , on expression typing slices:

$$[\varsigma_1 \mid \gamma_1] \sqsubseteq [\varsigma_2 \mid \gamma_2] \iff \varsigma_1 \sqsubseteq \varsigma_2 \text{ and } \gamma_1 \subseteq \gamma_2$$

expression typing slices will often be grouped and indexed upon expressions and typing contexts,  $P_e^\Gamma$  which contains all slices  $\rho \sqsubseteq (e, \Gamma)$ . So, the set  $P_e^\Gamma$  forms a lattice (**cite**) with unique least upper bound  $[e, \Gamma]$  and greatest lower bound  $[\square, \emptyset]$ . Similarly, an element  $\rho$  in  $P_e^\Gamma$  can be referred to as a expression typing slice of  $e$  under  $\Gamma$ .

### 3.1.2 Context Typing Slices

**add pattern context.**

Formally, an *expression context*  $\mathcal{C}$  is an expressions with *exactly one* sub-term marked as  $\bigcirc$ :<sup>3</sup>

$$\mathcal{C} ::= \bigcirc \mid \lambda x : \tau. \mathcal{C} \mid \lambda x. \mathcal{C} \mid \mathcal{C}(e) \mid e(\mathcal{C}) \mid \mathcal{C} : \tau$$

Where  $\mathcal{C}\{e\}$  substitutes expression  $e$  for the mark  $\bigcirc$  in  $\mathcal{C}$ , the result of this is necessarily an expression. Additionally, contexts are composable: substituting a context into a context,  $\mathcal{C}_1\{\mathcal{C}_2\}$  produces another valid context, notate this by  $\mathcal{C}_1 \circ \mathcal{C}_2$ <sup>4</sup>.

Similarly to expressions, contexts can be extended to *context slices* by allowing slices within:

$$c ::= \bigcirc \mid \lambda p : v. c \mid c(\varsigma) \mid \varsigma(c) \mid c : v$$

However, the precision relation  $\sqsubseteq$  is defined differently, requiring that the mark  $\bigcirc$  must remain in the same position in the context structurally speaking. For example  $\bigcirc(\square) \sqsubseteq \bigcirc(1)$ , but  $\bigcirc \not\sqsubseteq \bigcirc(1)$ . This can be concisely defined by *extensionality* (**cite**):

**Definition 1 (Context Precision)** *If  $c'$  and  $c$  are context slices, then  $c' \sqsubseteq c$  if and only if, for all expressions  $e$ , that  $c'\{e\} \sqsubseteq c\{e\}$ .*

Again, we refer to a context slice  $c$  of  $\mathcal{C}$  as one satisfying that  $c' \sqsubseteq \mathcal{C}$ .

We also get that filling contexts preserves the precision relations both on expression slices and context slices:

**Conjecture 1 (Context Filling Preserves Precision)** *For expression slice  $\varsigma$  and context slice  $c$ . Then if we have slices  $\varsigma' \sqsubseteq \varsigma$ ,  $c' \sqsubseteq c$  then also  $c'\{\varsigma'\} \sqsubseteq c\{\varsigma\}$ .*

Therefore, context slices  $c$  can be thought of as monotone function (**cite**)...

Show that composition is also preserved over precision, i.e. it is a functor.

---

<sup>3</sup>The two separate syntax definition for application allow a *mark* to be in either the left or right expression, but *not both*.

<sup>4</sup>Context can alternatively be thought of as functions from expressions to expressions.

Make some references to category theory, i.e. category of slices with morphisms being context slices. Or that slices form categories on expression  $e$  and contexts are a functor between expression typing slice categories. i.e. contexts are monotonic functions

**rewrite** The accompanying notion of a *typing assumption slice* can be extended to functions on typing assumptions. This function can represent what typing assumptions need to be **added**, or can be *removed* when placing  $e$  in it's context slice.

Functions can be composed and a precision partial order can also be defined via extensionality:

**Definition 2 (Function Precision)** If  $f'$  and  $f$  are functions, then  $f' \sqsubseteq f$  if and only if, for all typing contexts  $\Gamma$ , that  $f'(\Gamma) \subseteq f(\Gamma)$ .

Again, such functions are monotone (find the name of this mathematical property... sorta an extended monotonicity):

**Conjecture 2 (Function Application Preserves Precision)** For typing context  $\Gamma$  and function  $f$ . Then if we have slices  $\Gamma' \subseteq \Gamma$ ,  $f' \sqsubseteq f$  then also  $f'(\Gamma') \sqsubseteq f(\Gamma)$ .

This pair of context slice and function  $f$  will be referred to as a *context slice* and notated  $p^f$ , should  $f$  be the identity it may be omitted in shorthand.

Extend composition to program contexts and substitution of expression typing slices. Again as slices are a superset of expressions, then this extends to expression etc.

When

### 3.1.3 Type-Indexed Slices

Do type-indexed expressions slices actually need contexts on the sub-slices? Are these every not claculable from the rule they are being used in

Have context i.e. contexts with a  $_$  and let the syntax write it directly as a *type-indexed context slice*, i.e. a type-indexed slice, but with the slice  $\rho_s$  replaced with  $\rho_s$ . Then allow easy syntax to create from a type indexed slice i.e.

$$(p\{? \mid \rho\})(\bigcirc) = p\{? \mid \rho(\bigcirc)\}$$

Reverse composition order for this?? Also, syntax for going from indexed context to indexed expression i.e.  $\{\}$

For *criteria 3 and cast slicing*, there is a need to decompose slices to find sub-slices which contribute to specific portions of a compound type. For example, which part of the expression typing slice was related to the argument type of a function specifically.

#### Give EXAMPLE

A *type(-indexed) slice*  $s$  consists of: a expression typing slice, a context slice, and a *type index*  $i$ . This index is either an *atomic* type label or is *compound*, consisting of type slices conforming to the structure of types:

$$i ::= ? \mid b \mid s \rightarrow s$$

$$s ::= p\{i \mid \rho\}$$

The type that a type slice  $s$  represents is the slice retaining only its type labels. This will be notated by  $\llbracket s \rrbracket$ , defined inductively:

$$\begin{aligned}\llbracket p\{? \mid \rho\} \rrbracket &= ? \quad \llbracket p\{b \mid \rho\} \rrbracket = b \\ \llbracket p\{s_1 \rightarrow s_2 \mid \rho\} \rrbracket &= \llbracket s_1 \rrbracket \rightarrow \llbracket s_2 \rrbracket\end{aligned}$$

This same notation will also be used to extract the type of a type index  $i$ , similarly defined.

A term  $e$  in some context  $\mathcal{C}$  will be associated with a *type slice* with the meaning that  $\rho$  contains an expression typing slice for typing  $e$  and  $p$  contains a context slice for typing  $e$  in context  $\mathcal{C}$  according to some criterion. Typically the context slice would correspond to type analysis and the expression typing slice would correspond to type synthesis.

The compound type slices must satisfy the crucial property that the sub-terms are sub-slices of  $\rho$ . That is:

$$p\{p_1\{i_1 \mid \rho_1\} \rightarrow p_2\{i_2 \mid \rho_2\} \mid \rho\} \implies p_1\{\rho_1\} \sqsubseteq \rho \text{ and } p_2\{\rho_2\} \sqsubseteq \rho$$

The precision relation can be extended to slices pointwise upon the expression typing slice and context slice for atomic types  $a$  (i.e.  $a ::= ? \mid b$ ):

$$p'\{a \mid \rho'\} \sqsubseteq p\{a \mid \rho\} \iff p' \sqsubseteq p \text{ and } \rho' \sqsubseteq \rho$$

And recursively for compound slices:<sup>5</sup>

$$\begin{aligned}p'\{s'_1 \rightarrow s'_2 \mid \rho'\} \sqsubseteq p\{s_1 \rightarrow s_2 \mid \rho\} &\iff p' \sqsubseteq p, \rho' \sqsubseteq \rho, \\ &\quad s'_1 \sqsubseteq s_1, \text{ and } s'_2 \sqsubseteq s_2\end{aligned}$$

Composition of expression typing slices to the outer context is possible,  $(p' \circ p)\{i \mid \rho\}$ , and is notated shorthand as  $p'\{s\}$  for  $s = p\{i \mid \rho\}$ .

Additionally, if  $p$  is empty,  $\circ^\emptyset$ , a type slice may be notated without it:  $i \mid \rho$ . Equally, when  $\rho$  is empty,  $\square^\emptyset$ , then notate  $p'\{i\}$ . This means that if both  $p, \rho$  are both empty then we have  $i$  which is syntactically identical to types  $\tau$ , so we can trivially treat types as *empty type slices*.

Then function matching  $\blacktriangleright \rightarrow$  can be extended to slices in multiple different ways with different uses depending on the context, see the appendix **ref**.

### 3.1.4 Criterion 1: Synthesis Slices

For *synthesis type slices* we consider an expression synthesising a type  $\tau$  under some context  $\Gamma$ :

$$\Gamma \vdash e \Rightarrow \tau$$

And consider the slices in  $P_e^\Gamma$  and attempt to find the minimum slice  $\rho = [\varsigma \mid \gamma]$  constraining that  $\rho$  also synthesises the same type  $\tau$  under the restricted context  $\gamma$ :

$$\gamma \vdash \varsigma \Rightarrow \tau$$

Where minimality requires that no other (strictly) less precise slice satisfies the criterion. That is: for any slice  $\rho' = [\varsigma' \mid \gamma']$ , if  $\gamma' \vdash \varsigma' \Rightarrow \tau$  and  $\rho' \sqsubseteq \rho$ , then  $\rho' = \rho$ .

**GIVE CONCRETE EXAMPLE HERE, use highlighting**

I conjecture that, under the Hazel type system, there exists a unique minimum slice for each  $\Gamma \vdash e \Rightarrow \tau$ :<sup>6</sup>

<sup>5</sup>Note, function arguments are *covariant* for this.

<sup>6</sup>Would follow from uniqueness of typing derivations in Hazel.

**Conjecture 3 (Uniqueness)** *If  $\rho$  and  $\rho'$  are minimum synthesis slices for  $\Gamma \vdash e \Rightarrow \tau$ , then  $\rho = \rho'$ .*

These slices can be found by omitting portions of the program which are *type checked*. If,  $\Gamma \vdash e \Leftarrow \tau$ , then by use of the subsumption rule we also have that  $\Gamma \vdash \square \Leftarrow \tau$ :

$$\text{Subsumption} \frac{\Gamma \vdash \square \Rightarrow ? \quad \tau \sim ?}{\Gamma \vdash e \Leftarrow \tau}$$

As the dynamic type is consistent with any type:  $? \sim \tau$ .

Then, to find the *minimum synthesis slice*, we can mimic the Hazel type synthesis rules (see fig. A.2), replacing uses of type analysis with gaps. Creating a judgement  $\Gamma \vdash e \Rightarrow \tau \dashv \rho$  meaning: *e that synthesises type  $\tau$  under context  $\Gamma$  produces minimum synthesis slice  $\rho$ .*

To demonstrate, the expression slice of a variable  $x$  can only be either  $x$ , requiring the use of  $x : \tau$  from the context:

$$\text{SVar} \frac{x : \tau \in \Gamma \quad \tau \neq ?}{\Gamma \vdash x \Rightarrow \tau \dashv [x \mid x : \tau]}$$

But if  $x : ?$ , then the (empty) slice  $[\square, \emptyset]$  also synthesises  $?$ , so instead use this.

For functions, we can recursively find the slice of the function body (which synthesises it's type in the original rules, hence having a minimum synthesis slice) and place inside a function. If the assumption  $x : \tau_1$  was *required* in synthesising that type, then this name must be present in the expression slice and the context slice no longer requires this assumption to type check the sliced function:

$$\text{SFun} \frac{\Gamma, x : \tau_1 \vdash e \Rightarrow \tau_2 \dashv [\varsigma \mid \gamma, x : \tau_1]}{\Gamma \vdash \lambda x : \tau_1. e \Rightarrow \tau_1 \rightarrow \tau_2 \dashv [\lambda x : \tau_1. \varsigma \mid \gamma]}$$

Otherwise, if  $\gamma$  does not use variable  $x$  then this binding may be omitted:

$$\text{SFunConst} \frac{\Gamma, x : \tau_1 \vdash e \Rightarrow \tau_2 \dashv [\varsigma \mid \gamma] \quad x \notin \text{dom}(\gamma)}{\Gamma \vdash \lambda x : \tau_1. e \Rightarrow \tau_1 \rightarrow \tau_2 \dashv [\lambda \square : \tau_1. \varsigma \mid \gamma]}$$

For function applications we can simply omit the argument, while the slice for the function can be obtained as it synthesises it's type.

$$\text{SApp} \frac{\Gamma \vdash e_1 \Rightarrow \tau_1 \dashv [\varsigma_1 \mid \gamma_1]}{\Gamma \vdash e_1(e_2) \Rightarrow \tau \dashv [\varsigma_1(\square) \mid \gamma_1]}$$

The remaining rules are in fig. B.1.

It is *expected* (**Proof TODO**) that these rules do indeed always produce a slice for any expression which synthesises a type, and that this slice is minimal:

**Conjecture 4 (Correctness)** *If  $\Gamma \vdash e \Rightarrow \tau$  then:*

- $\Gamma \vdash e \Rightarrow \tau \dashv \rho$  where  $\rho = [\varsigma \mid \gamma]$  with  $\gamma \vdash \varsigma \Rightarrow \tau$ .
- For any  $\rho' = [\varsigma' \mid \gamma'] \sqsubseteq [e \mid \Gamma]$  such that  $\gamma' \vdash \varsigma' \Rightarrow \tau$  then  $\rho \sqsubseteq \rho'$ .

## Extension to Type-Indexed Slices

This mechanism can be trivially extended to type-indexed slices, where types being synthesised can be replaced by slices directly, i.e. *slice synthesis*. See the appendix **ref AND FIX**.

The only interesting case is the fact that slices for argument types to functions can now be accessed, so must be represented:

### 3.1.5 Criterion 2: Analysis Slices

A similar idea can be devised for analysis slices. Essentially, we do the opposite of *criterion 1* and omit sub-terms where *synthesis* was used. The objective is to show *why* a term is required to be checking against a type.

The useful notion to represent these are *context slices*. It is the terms immediately *around* the sub-term where the type checking is enforced:

For example, when checking this annotated term:

$$(\lambda x. \underline{\text{⌈}}^u) : \text{Bool} \rightarrow \text{Int}$$

The *inner hole term*  $\underline{\text{⌈}}^u$  (underlined from now on) is required to be consistent with  $\text{Int}$  due to the annotation. The context slice will then be:

$$(\lambda x. \underline{\text{⌈}}^u) : \text{Bool} \rightarrow \text{Int}$$

Intuitively, this means that the *contextual* reason for  $\underline{\text{⌈}}^u$  to be required to be an  $\text{Int}$  is: that it is within a function which the annotation enforced to check against  $\text{Bool} \rightarrow \text{Int}$ , of which only the return type ( $\text{Int}$ ) is relevant.

In other words, if the slice was type synthesised, then the hole term would still be *required* to check against  $\text{Int}$ .

For this criterion we consider only the smallest context that resulted in a term being type checked, for example in the following term:

$$\underline{1} : \text{Int} : ? : \text{Bool}$$

The context that enforced 1 to be checked against an  $\text{Int}$  was *only* the inner annotation. We refer to this as the *checking context*. The term when inside it's checking context will always synthesise a type.<sup>7</sup>

**These definitions below are verbose and it might be better to just leave it intuitive for this, with definition deferred to appendix.**

To represent this, we use a notion of a types *flowing* from other types inside a derivation, i.e. if a type is decomposed, then it's parts *flow* from the complete type. This can be formalised by creating a *type flow* rules (**Ref to appendix**).<sup>8</sup> Under this flow, every checked type  $\tau'$  in a derivation has an *origin* synthesis rule producing *first* type which  $\tau'$  flows from.

**Maybe give example?**

Then, the *checking context* we want to consider is that of the conclusion of the rule containing the source of the type:

**Definition 3 (Checking Context)** For a derivation  $\Gamma \vdash e \Rightarrow \tau$  containing a sub-derivation  $\Gamma'' \vdash e'' \Leftarrow \tau''$  and where the origin of  $\tau''$  is another sub-derivation  $\Gamma' \vdash e' \Rightarrow \tau'$ . Then either:

- $e''$  is a sub-term of  $e'$ : the checking context of  $e''$  is  $C$  such that  $e' = C\{e''\}$ .
- Otherwise,  $\Gamma'' \vdash e'' \Rightarrow \tau''$  must be a premise in another rule whose conclusion is a synthesis  $\Gamma''' \vdash e''' \Rightarrow \tau'''$  where  $e'$  is a sub-term of  $e'''$ . The checking context is  $C$  such that  $e''' = C\{e''\}$

<sup>7</sup>If it analysed against a type, then this would have it's own checking context. We merge these contexts.

<sup>8</sup>This type flow is closely related to mode correctness.

It is clear that this must then be the smallest context containing derivations of both the *checked expression* and its *origin*. This checking context can be defined more intuitively using rules (see **appendix**) and proven to coincide with the definition above.

An *analysis slice* is a slice of a checked term's *checking context*:

**Definition 4 (Analysis Slice)** For a derivation  $\Gamma \vdash e \Rightarrow \tau$ , containing a sub-derivation  $\Gamma' \vdash e' \Leftarrow \tau'$  with checking context  $\mathcal{C}$ . Then we have that  $\Gamma \vdash \mathcal{C}\{e'\} \Rightarrow \tau''$ .

An *analysis slice* of  $e'$  is a program context slice  $c^f$  such that:

- $c$  is a slice of  $\mathcal{C}$ , that is,  $c \sqsubseteq \mathcal{C}$ .
- $f$  is a slice of  $\Gamma' \mapsto \Gamma$ . **Formalise this better...**
- $c\{e'\}$  synthesises a type consistent<sup>9</sup> with  $\tau''$  under typing context  $f(\Gamma')$  and still contains the sub-derivation checking  $e'$  against  $\tau'$  in checking context  $c$ :

$$f(\Gamma') \vdash c\{e'\} \Rightarrow \tau''', \quad \tau''' \sim \tau'', \quad \Gamma' \vdash e' \Leftarrow \tau'$$

The *minimum analysis slice* is just the minimum under the precision ordering  $\sqsubseteq$ . And it must be unique:

**Conjecture 5 (Uniqueness)** If  $\rho$  and  $\rho'$  are minimum analysis slices for sub-terms  $e'$  of  $e$  where  $\Gamma \vdash e \Leftarrow \tau$ , then  $\rho = \rho'$ .

This can again be represented by a judgement read as, *e which type checks against  $\tau$  in checking context  $\mathcal{C}$  has analysis slice  $p$* :

$$\Gamma; \mathcal{C} \vdash e \Leftarrow \tau \dashv p$$

There are two situations which enforce *checking contexts*, annotations:

$$\frac{\Gamma \vdash e \Leftarrow \tau}{\Gamma; \circ : \tau \vdash e \Leftarrow \tau \dashv \circ : \tau}$$

And applications, for which we need a slice of the application for the *argument* type of the function, which has previously been devised for *type-indexed synthesis slices* (**ref**):

$$\frac{\Gamma \vdash e_1 \dashv \Rightarrow p\{c_1^{f_1}\{i_1 \mid \varsigma_1^{\gamma_1}\} \rightarrow s_2 \mid \rho\} \quad \Gamma \vdash e_2 \Leftarrow \llbracket i_1 \rrbracket}{\Gamma; e_1(\circ) \vdash e_2 \Leftarrow \llbracket i_1 \rrbracket \dashv (c_1\{\varsigma_1\})(\circ)^{f_1}}$$

That is, if  $e_1$  synthesises some type  $\tau_1 \rightarrow \tau_2$  (i.e.  $\llbracket i_1 \rrbracket \rightarrow \llbracket s_2 \rrbracket$ ), then the slice for  $\tau_1$  in the context as a slice  $e_1$  is  $c_1\{\varsigma_1\}$ .

Finally, type analysis rules pass the context down (i.e. sub-terms have the same checking context) and also records that the context now needs to remove the  $x : \tau_1$  assumption:

$$\frac{\Gamma; \mathcal{C} \vdash \lambda x. e \Leftarrow \tau_1 \rightarrow \tau_2 \dashv p}{\Gamma, x : \tau_1; \mathcal{C} \circ (\lambda x. \circ) \vdash e \Leftarrow \tau_2 \dashv \text{ret}(p) \circ (\lambda x. \circ)^{(-)\backslash x:\tau_1}}$$

**Todo, case for if x is not needed...**

Where  $\text{ret}(p)$  takes the part of the slice that was required in synthesising  $\tau_2$ , defined in **appendix**. This direct definition is quite complex; checking against *type-indexed slices* representing the synthesis of  $\tau_1 \rightarrow \tau_2$  is *much easier*.

This definition does indeed find the minimum analysis slice:

---

<sup>9</sup> $e'$  within the sliced context might now synthesise a *less precise* type.

**Conjecture 6 (Correctness)** *If  $\Gamma \vdash e \Rightarrow \tau$  with sub-derivation  $\Gamma \vdash e' \Leftarrow \tau'$  in checking context  $C$  then we also have that  $\Gamma; C \vdash e' \Leftarrow \tau' \dashv p$  and:*

- *$p$  is an analysis slice for  $e'$ .*
- *For any  $p' = [c' \mid \gamma'] \sqsubseteq [C \mid \Gamma]$  such that  $p'$  is an analysis slice of  $e'$  then  $p \sqsubseteq p'$ .*

### Extension to Type-Indexed Slices

As mentioned previously, using *type-indexed synthesis slices* calculated via *criterion 1* as input makes analysis slices much easier to calculate.

Additionally, the rules in this form end up being more closely tied to the Hazel typing rules and hence easier to formalise.

See appendix

### 3.1.6 Criterion 3: Contribution Slices

This criterion aims to highlight all regions of code which *contribute* to the given type (either synthesised or analysed). Where *contribute* means that if the sub-term changed its type, then the overall term would<sup>10</sup> also, or would become ill-typed. Importantly, we also consider *contexts* for expression which are analysed, again considering any component terms which having their type changed would result in an error when trying to analyse against the type. For example in the following term:

$$(\lambda f : \text{Int} \rightarrow ?. f(1))(\lambda x : \text{Int}. x)$$

The terms which *contribute* to the *second*<sup>11</sup> lambda term checking successfully against  $\text{Int} \rightarrow ?$  is everything *except* the  $x$  term, while context slice is just the annotation (and required structural constructs). Highlighting related to synthesis will be a darker shade:

$$(\lambda f : \text{Int} \rightarrow ?. f(1)) \quad (\lambda x : \text{Int}. x)$$

Notice that, in any typing derivation the only sub-terms which *can* have their type changed without causing the rule to no longer apply are those which use type *consistency*.<sup>12</sup> The only such rule is *subsumption*. Further, the only time a term could be changed to *any* type and still remain valid is when it is checked for consistency with the dynamic type  $?$ .

Therefore, this criterion just *omits all dynamically annotated regions* of the program.<sup>13</sup> And, the contextual part of the slices are just *analysis slices*.

**Definition 5 (Contribution Slices)** *For  $\Gamma \vdash e \Rightarrow \tau$  containing sub-derivation  $\Gamma' \vdash e' \Leftarrow \tau'$  with checking context  $C$ .*

*A contribution slice of  $e'$  is an analysis slice for  $e'$  in  $C$  paired with an expression typing slice  $\varsigma^\gamma$  such that:*

- *$\varsigma$  is a slice of  $e'$ , that  $\varsigma \sqsubseteq e'$ .*

<sup>10</sup>No matter which type it was changed to specifically.

<sup>11</sup>Underlined below from now on.

<sup>12</sup>Note that this logic does *not* extend to globally inferred languages.

<sup>13</sup>But does not omit the dynamic annotations themselves.

- Under restricted typing context  $\gamma$ , that  $\varsigma$  checks against any  $\tau'_2$  at least as precise as  $\tau'$ :<sup>14</sup>

$$\forall \tau'_2. \tau' \sqsubseteq \tau'_2 \implies \gamma \vdash e' \Leftarrow \tau'_2$$

A contribution slice for a sub-term  $e''$  involved in sub-derivation  $\Gamma'' \vdash e'' \Rightarrow \tau''$  where  $e'' \neq e'$  is an expression typing slice  $\varsigma''^{\gamma''}$  which also synthesises  $\tau''$  under  $\gamma''$ , that  $\gamma'' \vdash \varsigma'' \Rightarrow \tau''$ . Further, any sub-term of  $e''$  which has a contribution slice of the above variety, is replaced inside  $\varsigma$  by that corresponding expression typing slice.

This is most naturally calculated using *type-indexed slices* exactly replicating the Hazel typing rules:

**Think more about type indexed context slices. Think how to reconstruct**

$$\begin{array}{c} \text{SConst} \frac{}{\Gamma \vdash c \dashv_{\Rightarrow} b \mid c} \quad \text{SVar} \frac{x : \tau \in \Gamma}{\Gamma \vdash x \dashv_{\Rightarrow} \text{map}(x^{\{x:\tau\}}, \tau)} \\ \\ s_1 = (\square : \bigcirc) \circ \text{annot}(\tau_1) \quad \Gamma, x : \tau_1 \vdash e \dashv_{\Rightarrow} s_2 \\ s_2 = i_2 \mid \varsigma^\gamma \quad x \blacktriangleright_\gamma p \\ \text{SFun} \frac{}{\Gamma \vdash \lambda x : \tau_1. e \dashv_{\Rightarrow} (\lambda \bigcirc. \square) \circ s_1 \rightarrow (\lambda p : \tau_1. \bigcirc) \circ s_2 \mid (\lambda p : \tau_1. \varsigma)^{\gamma \setminus x:\tau_1}} \end{array}$$

**TODO: fix SFun annotations for the argument slice, they need to remove unused requirements?**

$$\begin{array}{c} \Gamma \vdash e_1 \dashv_{\Rightarrow} s_1 \quad s_1 \blacktriangleright_{\rightarrow} s_2 \rightarrow s \\ \Gamma \vdash e_2 \Leftarrow_{s_2} (\bigcirc) \dashv_{\Rightarrow} s'_2 \\ \text{SApp} \frac{}{\Gamma \vdash e_1(e_2) \dashv_{\Rightarrow} \text{app}(s'_2)} \\ \\ \text{SEHole} \frac{}{\Gamma \vdash \llbracket \bigcirc \rrbracket^u \dashv_{\Rightarrow} ? \mid \llbracket \bigcirc \rrbracket^u} \quad \text{SNEHole} \frac{\Gamma \vdash e \dashv_{\Rightarrow} p\{i \mid \varsigma^\gamma\}}{\Gamma \vdash \llbracket e \rrbracket^u \dashv_{\Rightarrow} ? \mid \llbracket \varsigma \rrbracket^{u\gamma}} \\ \\ c = \bigcirc : \text{annot}(\tau) \quad \Gamma \vdash e \Leftarrow_{\mathcal{J}} \dashv_{\Rightarrow} s \\ \text{SAsc} \frac{}{\Gamma \vdash e : \tau \Rightarrow \text{app}(s)} \\ \\ \mathcal{J} \blacktriangleright_{\rightarrow} \mathcal{J}_1 \rightarrow \mathcal{J}_2 \\ \Gamma, x : \llbracket \mathcal{J}_1 \rrbracket \vdash e \Leftarrow_{\mathcal{J}_2} \circ (\lambda x. \bigcirc) \dashv_{\Rightarrow} s_2 \\ \text{AFun} \frac{}{\Gamma \vdash \lambda x. e \Leftarrow_{\mathcal{J}} \dashv_{\Rightarrow} \mathcal{J}_1 \{ \lambda \square. \square \} \rightarrow s_2} \\ \\ \Gamma \vdash e \dashv_{\Rightarrow} s \\ \llbracket s \rrbracket \sim \llbracket \mathcal{J} \rrbracket \\ \text{ASubsume} \frac{}{\Gamma \vdash e \Leftarrow_{\mathcal{J}} \dashv_{\Rightarrow} \bigsqcup \text{static}(\llbracket \mathcal{J} \rrbracket, s)} \end{array}$$

**Figure 3.1:** Contribution Slices

Where  $\text{map}(\rho, \tau)$  creates a type-indexed slice of type  $\tau$  with the slice context  $\bigcirc$  and expression typing slice  $\rho$  tagged on all components of  $\tau$ . Annot is as defined in criterion 1 extended to type-indexed slices.  $x \blacktriangleright_\gamma = p$  matches  $p$  with  $x$  if  $x \in \text{dom}(\gamma)$ , otherwise returns  $\square$ .  $\blacktriangleright_{\rightarrow}$  is extended to slices as follows:

$$\rho\{s_1 \rightarrow s_2 \mid \rho\} \blacktriangleright_{\rightarrow} p \circ s_1 \rightarrow p \circ s_2$$

<sup>14</sup>Essentially, sub-terms that check against  $?$  also synthesise  $?$ . Defined this way to include the case of unannotated lambdas (which do not synthesise).

$$p\{? \mid \rho\} \blacktriangleright \rightarrow p\{? \mid \rho\} \rightarrow p\{? \mid \rho\}$$

static replaces a (sub)slice term if it is in the position of a  $?$  on the input. Reconstructing the term is just taking the join down one level (**PROVE This**).

### 3.1.7 Join Types

The Hazel core calculus is very primitive, only consisting of *base types*, *annotations*, and *functions*. Extensions to gradual types [12], and Hazel [9]<sup>15</sup>: *if* expressions, *pattern matching*, *sum types* etc. all require<sup>16</sup> *join types*.

A join of two types  $\tau_1 \sqcup \tau_2$  (if one exists) is the least precise (most general) type that more precise than both  $\tau_1, \tau_2$ : that  $\tau_1 \sqsubseteq \tau_1 \sqcup \tau_2$  and  $\tau_2 \sqsubseteq \tau_1 \sqcup \tau_2$ . Therefore, the join is therefore is consistent with both  $\tau_1, \tau_2$ . Type consistency can be reformulated in terms of joins:  $\tau_1, \tau_2$  are consistent *if and only if* they have a join. This is the *order-theoretic* (**cite**) join with respect to the precision partial order on types. For example, the type of an *if statement* would be the join of the types of it's branches.

These add an additional way to generate a *new type* other than by synthesis or from annotations.

Hence, type flow needs to be extended to allow these. Equally, slices themselves can be joined if they have common contexts (though there is a decision whether to include both branches of a join).

### 3.1.8 Type-Indexed Slicing Context

It seems natural to extend the typing context to a type-indexed slicing context. Then, when accessing typing assumptions via variable references, the source information about the derivation for this type is revealed. But, the problem is, there is no context propagated, these slices are slices of the original term; propagating all this would be a big pain.

## 3.2 Cast Slicing Theory

Fairly trivial, just treat slices as types and decompose accordingly. The whole reason of indexing by type was to allow this.

The idea of it being a minimal expression typing slice producing the same cast doesn't really work here due to dynamics. Explore the maths of this. Either way, it is a useful construct in practice. Exploring this in more detail, looking at *dynamic program slicing* could be a good future direction.

**Mention and compare with blame tracking**

### 3.2.1 Indexing Slices by Types

### 3.2.2 Elaboration

All casts inserted come from type checking, so can be sliced

---

<sup>15</sup>Here as the *meet* of the opposite of my *precision* order.

<sup>16</sup>Or are easiest formulated with.

### 3.2.3 Dynamics

Ground type casts will be added, but their addition is purely technical and we can treat their reasoning to just be extracting the relevant portion of the original non-ground type.

### 3.2.4 Cast Dependence

This in combination with the indexed slices could have some nice mathematical properties.

Though, these would need to retrieve information about parts of slices that were lost when decomposing slices. i.e. when a slice  $\tau_1 \rightarrow \tau_2$  extracts the argument type  $\tau_2$ , the slicing criterions lose track of the original lambda binding. A way to reinsert these bindings such that we get a minimal term which *Evaluates to the same cast* e.g. But this will have lots of technicalities with correctly tracking the restricted contexts  $\gamma'$  for closures (i.e. functions returning functions which have been applied once). **TALK ABOUT THIS IN THE FURTHER DIRECTIONS SECTION.**

## 3.3 Type Slicing Implementation

Here I detail how the theories above were adapted to produce an implementation for Hazel.

### 3.3.1 Hazel Terms

Hazel represents its abstract syntax tree (AST) (**cite**) in a standard way by creating a mutually recursive algebraic data-type (**cite**).

Terms are classified into similar groups as described in the calculus (see section 2.1.2), though combining external and internal expressions, and adding *patterns*:

- **Expressions:** The primary encompassing term including: constructors<sup>17</sup>, holes, operators, variables, let bindings, functions & closures, type functions, type aliases, pattern match expressions, casts, explicit fix<sup>18</sup> expression.
- **Types:** Unknown type<sup>19</sup>, base types, function types, product types, record types, sum types, type variables, universal types, recursive types.
- **Patterns:** Destructuring constructs for bindings, used in functions, match statements, and let bindings, including: Holes, variables (to bind values to), wildcard, constructors, annotations (enforcing type requirements on bound variables).
- **Closure Environments:** a closure mapping variables to their assigned values in it's syntactic context.

For example fig. 3.2 shows a let binding expression whose binding is a tuple pattern (in blue) binding two variables  $\mathbf{x}$ ,  $\mathbf{y}$  annotated with a type (in purple).

---

<sup>17</sup>The basic language constructs: integers, lists, labelled tuples etc. Also, user-defined constructors via sum types.

<sup>18</sup>Fixed point combinator for recursion.

<sup>19</sup>Either dynamic type, or a type hole.

```
let (x, y) : (Int, Bool) = (1, true) in x
```

**Figure 3.2:** Let binding a tuple with a type annotation.

Every term (and sub-term) is annotated with an *identifier* (ID, `Id.t`) in the AST which refers back to the syntax structure tree. In a sense, this is the equivalent of *code locations*, but Hazel is edited via a structure editor.

### 3.3.2 Type Slice Data-Type

I detail here *how* and *why* I implement type slices for Hazel.

#### Expression slices as ASTs

Actually the below might be inaccurate, check the structure of the typing system to see if we would ever need to re-traverse an AST?

Either way, there is opportunity to speak about persistence with how type slices are combined and decomposed and how they overlap. etc.

Directly storing expression slices directly as ASTs is both *space* and *time inefficient*. The AST type is a persistent data structures [46, ch. 2], meaning that any update to the tree will retain both the old and updated tree. All nodes on the path to the updated sub-tree must be copied; for example, fig. 3.3 shows how a node G (in blue) can be sliced off from the tree while the old tree (in black) and the new tree (in red) both persist and share some unmodified nodes structurally. Expression slices do exactly this slicing operation extensively, so would require significant copying.

**Figure 3.3:** Persistent Tree

Maybe talk about a destructive version (always retain the original tree but from the perspective of various cursors

There are ways to partially avoid this, for example the *Zipper* data structure represents trees by from the perspective of a *cursor* node rather than the *root*. The part of the tree above the cursor is stored as an *upside-down*. This allows the cursor to be

We can derive an analogous *one-hole context* type for the AST by *differentiating* it's type [39, 31].

**Zippers only useful if we need access to the parent node which cannot just be done by passing down info.**

However, we still have to copy nodes when shifting the cursor; during type-checking all nodes will be visited by the cursor so we would get at least a *doubling* in space used. Additionally, converting a zipper back into a tree would take linear time<sup>20</sup> and still require copying the path to the cursor as before.<sup>21</sup>

**Produce Tikz Diagram Here.**

**Figure 3.4:** Tree Zipper

However, the biggest issue is that expressions slices have *multiple* gaps, so cannot be represented by a *one-hole* context. Further, the slices vary in their number of holes, so generalising one-hole contexts to two-hole contexts etc. is not an option as each would require it's own distinct type. There are extensions to zippers allowing multiple holes which would work, *multi-zippers* [5] for example, but has large constant overhead and would be very complicated to implement for such an extensive AST.

## Unstructured Code Slices

With this in mind, given that the structure of expression slices does not actually matter for highlighting<sup>22</sup>, I represent slices indirectly by these IDs in an *unstructured* list, referred to now as a *code slice* (`code_slice` type).

Additionally, this has the side effect of allowing more *granular* control over slices, as they now need not conform with the structure of expressions which is taken advantage of to reduce slice size, **(ref to section discussing this + evaluation)**.

Equally, the typing assumption slices are only required for formal type checking, however I maintain these is code slices to allow for different UI styling of slices originating from the use of the typing context (bold border).

## Type-Indexed Slices

Cast slicing and contribution slices required *type-indexed* slices. I therefore tag type constructors with slices recursively, i.e.:

However, this did not model the structure of type slices particularly well. Slices are generally incrementally constructed. Synthesis slices build upon slices of sub-terms and analysis slices , demonstrated in fig. 3.6.

The original data-type works well for synthesis slices as the list data-type is persistent and sub-slices are never modified. But not for analysis slices, which require an id to be added to

---

<sup>20</sup>In the depth of the cursor.

<sup>21</sup>Still advantageous as it delays the copying only for when the slice is actually *used* in a way that requires this conversion. UI for slices would still work directly on the zipper structure without copying.

<sup>22</sup>Only matters for type checking slices, which always succeeds by design.

```

type typslice_typ_term =
  | Unknown
  | Arrow(slice_t, slice_t) // Function type
  | ... // Type constructors
and typslice_term = (typslice_typ_term, code_slice)
and typslice_t = IdTagged.t(slice_term)

```

**Figure 3.5:** Initial Type Slice Data-Type

*all* sub-slices. Hence, analysis slices had *quadratic* space complexity in the depth of the type (Get numbers in evaluation to show it being worse if possible).

```

let f : Int -> Int = fun x -> x in f(0)

```

Synthesis slice for  $f(0)$  is just constructed incrementally from the slices for 0 and  $f$ . Analysis slice for 0,  $f$  and all its sub-slices all depend upon the annotation and binding etc.

**Figure 3.6:** Slicing is Incremental

## Incremental Slices

Therefore, I explicitly represent slices incrementally, with two modes, for synthesis slice parts (termed *incremental slice tags*) and analysis slice parts (termed *global slice tags*).

I now tag each type constructor with incremental or global slices representing:

- Incremental Slice Tag: The slice of an expression is its sub-slices adding its incremental slice. But the sub-slices do not depend on the incremental slice.
- Global Slice Tag: All the sub-slices of this term depend on this slice.

So instead of tagging an id in an analysis slice to all subslices, I tag it only to the constructor as a *global slice*, and *lazily* tag it to sub-slices upon usage (during type destructuring).

We get the following type:

```

type typslice_typ_term =
  | Unknown
  | Arrow(slice_t, slice_t) // Function type
  | ... // Type constructors
and typslice_term =
  | SliceGlobal(slice_t, code_slice)
  | SliceIncr(slice_t, code_slice)
and typslice_t = IdTagged.t(typslice_term)

```

**Figure 3.7:** Incremental Slice Data-Type

A key change when using this model is that when deconstructing types via function matching, list matching, etc. used throughout type checking and unboxing, the global slice must be pushed inside the resulting deconstructed types. This ensures that no part of the analysis slice context is lost (**compare to function matching in the type-indexed slice theory**).

## Usability & Efficiency

The type was further changed and many utility functions were added to enforce invariants and to ease development.

**Empty Slices** Many type constructors have no associated incremental slice part (**example**), especially during evaluation. Equally, when type slicing is turned off. A **TypSlice**(typslice\_typ\_term) constructor is added to represent this case.

**Fully Empty Slices** For the case when type slicing is turned off we also know that *all* sub-slices are empty, and we get an isomorphism between slices and the original *type*. For convenience in integrating with existing code, a fourth slice type **Typ**(typ\_term) is added allowing a trivial and *efficient*<sup>23</sup> injection from types to typeslices by tagging with **Typ**. Note that this means the empty slices **TypSlice** no longer needs to include atomic types.<sup>24</sup>

**Slice Tag Duplicates** The previous formulation allowed structures a type constructor with multiple global slices. For example:

The possibility of any permutation of slices makes programming awkward when conceptually all we need is *at most one* global and incremental slice tag. I enforce this invariant by refining the type to the actual type used in the final implementation:<sup>25</sup> **TODO: Refactor code to use empty type-slices**

```
...
and typslice_empty_term = [
  | `Typ(typ_term)
  | `TypSlice(typslice_typ_term)
]
and typslice_incr_term = [
  | `Typ(typ_term)
  | `TypSlice(typslice_typ_term)
  | `SliceIncr(typslice_typ_term, code_slice)
]
and typslice_term = [
  | `Typ(typ_term)
  | `TypSlice(typslice_typ_term)
  | `SliceIncr(typslice_empty_term)
  | `SliceGlobal(typslice_incr_term, code_slice)
]
and typslice_t = IdTagged.t(typslice_term)
...
```

*Polymorphic Variants* [25, ch. 7.4], notated [ | ... ] are used here for convenience in incrementally writing functions, explained for an example *apply* function below. These are

---

<sup>23</sup>Conversion to the empty slice type would instead take linear time.

<sup>24</sup>These being equivalent to types, as no sub-slices exist.

<sup>25</sup>Modulo some insignificant refactorings.

variants which exhibit *row polymorphism* [47] [7, ch. 10.8] where these variants are related by a *structural subtyping* relation [51] where polymorphic variants of the same *structure*, with constructors of the same name and types, are subtypes.

We have that, `typslice_empty_term` is a subtype of `typslice_incr_term` which is a subtype of `typslice_term`. All other type constructors are either co-variant or contra-variant [49, ch. 2] with respect to the subtyping relation. For example, id tagging is covariant<sup>26</sup>, so an `IdTagged.t(typslice_incr_term)` is a subtype of `IdTagged.t(typslice_incr_term) = typslice_t.`

Equally, a function of type `typslice_incr_term → typslice_incr_term` is a subtype of `typslice_empty_term → typslice_term`, being contravariant in it's argument and covariant in it's result. This function subtyping property significantly reduces work in defining functions on this type as seen below.

**Utility Functions** Functions on slices often do not concern the slices, but only the structure of it's underlying type, for example in unboxing<sup>27</sup> (`ref to sec`). In which case it is more convenient to just write a `typ_term → α` and `typslice_term → α` function directly on the possible empty slice types.

An `apply` function is provided to apply this onto the slice term. See how the bottom two branches can both be passed into the `apply` function even though they have different types (but are both subtypes of `typslice_term`).

```
let rec apply = (f_typ, f_slc, s) =>
  switch (s) {
  | `Typ(ty) => f_typ(ty)
  | `TypSlice(slc) => f_slc(slc)
  | `SliceIncr(s, _) => apply(f_typ, f_slc, s)
  | `SliceGlobal(s, _) => apply(f_typ, f_slc, s)
  }
```

Similarly, mapping function which map a `typ_term → typ_term` and similar functions onto slices are provided while maintaining the slice tags. Another particularly useful one is a mapping function that maps `typ_term → typslice_term` etc. and merges the slices around the input term and the output slice of the mapped function. Other utility functions include wrapping functions, unpacking functions, matching functions etc.

## Type Slice Joins

Type joins are extensively used in the Hazel implementation for *branching statements*. The type of a branching statement is the *least specific* type which is still *at least as specific* as all the branches. This corresponds to the *lattice join* of the types of the branches with respect to the precision relation.

Previously in section 3.1.7, I stated how slices could be joined. To implement this, first any contextual code slices required to place the branches within a common context are wrapped onto the branch slices. Then the slices are joined, unioning the incremental code slices of branches.

---

<sup>26</sup>It is just a labelled pair type.

<sup>27</sup>e.g. checking if a slice is a *list* type.

For basic synthesis and analysis slices, I decide to take the code slices for each atomic type in the joined type from only *one* branch. This retains a complete explanation of *why* the joined type is synthesised/checked, but does *not* constitute a valid contribution slice.

This slicing is not as easy as just taking the slice of a single branch, as the most specific sub-parts of the joined type may come from differing branches. For example in fig. 3.8, the *then* branch has a type  $\text{Int} \rightarrow (?, \text{Int})$  and the *else* branch has type  $\text{Int} \rightarrow (\text{Int}, ?)$  meaning the joined type is  $\text{Int} \rightarrow (\text{Int}, \text{Int})$ . We can omit one<sup>28</sup> of the redundant annotations on the argument but still must retain a slice of the 0 term in both branches to get the  $(\text{Int}, \text{Int})$  slice.

*if ? then fun x : Int -> (? , 0) else fun x : Int -> (0, ?)*

**Figure 3.8:** Type Slice Join

The unstructured nature of code slices also allows the type constructors to select only *one* branch to take the slice from. The given figure would *not* highlight the function constructor in the *then* branch. However, this is not be a valid expression slice in the theoretic sense and could be confusing for the user (**discuss in evaluation, missing info**).

## Contribution Slices

To create a *contribution slice* (definition and correctness reasoning in section 3.1.6) we will need to combine analysis and synthesis slices on the same term that:

- Matches compound type constructor slice tags are combined.
- Atomic *dynamic* type parts of the *analysis slice* are retained in preference to the synthesis slice part.
- Other atomic type constructors have slices combined.

We get a type slice whose type is equivalent to the analysis slice, but includes relevant parts of the synthesis slice.

Use same example here as in theory

**Figure 3.9:** Contribution Slice

## Weak Head Normalisation

Describe where this is used and how slices do this. This subsection could be elided.

### 3.3.3 Static Type Checking

The Hazel implementation is *bidirectionally typed*. During type checking, the typing *mode* in which to check the term is specified with `Mode.t` type: *synthesising*<sup>29</sup> (**Syn**) or *analysing* (**Ana**(**Typ**.t)).

The type checker associates each term with a type information object `Info.t`, stored in a map by term id with efficient access. The *type information* stores the following info:

<sup>28</sup>The figure, and my implementation, omits the left branches.

<sup>29</sup>Additionally split into synthesising functions and type functions, but this detail is elided here.

- The term itself and it's ancestors.
- **Mode**: Typing expectations enforced by the context.
- **Self**: Information derived independent from the *mode*, e.g. synthesised type, or type errors arising from inconsistent branch types, syntax errors.
- **Typing context and co-context**. A co-context
- Status: Is it an error, what type of error? For example, inconsistency between type expectations and synthesised/actual type.
- **Type**: The *actual* type of the expression after *accounting for errors*. Errors are placed in holes, so synthesise the dynamic type.
- Constraints: Patterns also store constraints to determine redundant branches and exhaustive match statements, in the sense of [26, ch. 13]<sup>30</sup>. Hazel-specific details in [10].

As suggested by my slicing theory, I augment the four bolded fields to refer to type slices, returning type slices from synthesis and analysing directly against type slices. This results in wide-changing code, but I only detail the general workings here.

## Self

The *self* data-structure now returns *types slices* instead of *types*. Every expression construct which can be synthesised has a corresponding function in `Self.re` to construct the slice from it's sub-derivations (slices of synthesised types of sub-expressions). Hence, the synthesis slicing behaviour for each type of expression can be easily configured uniformly via editing these functions.

For example, the slice of a pattern matching statement, given slices of all it's branches (`tys`) is the join of it's branches wrapped in an incremental slice consisting of the ids of the match statement itself. Otherwise if the branches are inconsistent it returns a failure tagging the branch slices with ids of the branches:

```
let of_match =
  (ids: list(Id.t), ctx: Ctx.t, tys: list(TypSlice.t),
   c_ids: list(Id.t)): t =>
  switch (
    TypSlice.join_all(
      ~empty=~Typ(Unknown(Internal)) |> TypSlice.fresh,
      ctx,
      tys,
    )
  ) {
  | None => NoJoin(Id, add_source(c_ids, tys))
  | Some(ty) => Just(ty |> TypSlice.(wrap_incr(slice_of_ids(ids))))
  };
```

**Figure 3.10:** Match Statement `Self.t`

This stage also included factoring out some expectation-independent code from the type checking function which had been missed by others.

---

<sup>30</sup>Only present in the *first* edition.

```

let of_list = (ids: list(Id.t), ctx: Ctx.t, mode: t): t =>
  switch (mode) {
  | Syn
  | SynFun
  | SynTypFun => Syn
  | Ana(ty) =>
    Ana(TypSlice.(matched_list(ctx, ty)
      |> wrap_global(slice_of_ids(ids))))
  };

```

**Figure 3.11:** List Literal `Mode.t`

## Mode

The *mode* now analyses against *type slices* instead of *types*. Again, each construct which could deconstruct an analysing type has a corresponding function in `Mode.re` which outputs the mode(s) to check the inner expressions. The inner analysis slices are tagged with a *global*<sup>31</sup> slice tag describing *why* the slice was deconstructed. As mentioned before (**ref**), deconstructing types retains the contextual (global) parts of the analysis slice.

For example, I can deconstruct a list slice with a list matching function `matched_list`. Using this, the mode to check a term inside a *list literal* is the matched inner list slice wrapped (globally) in the ids of list literal itself (`ids`) which enforced this matching. We use this mode to check each element in the list literal.

## Typing (Co-)Context

The typing context and co-contexts are modified to use type slices, given that we now always have a slice to accompany a type in any situation.

Section 3.1.8 discusses one major consequence of allowing this. Slices for variables may now include the slice binding it's type.

This *deviates* from the theoretical notion of an expression slice: the structural context in which the variable is used is untracked when passing through the context. But, it is easy to implement using *unstructured* code slices and is a useful addition conceptually (**discuss in evaluation**).

## Type

The *type* field is extended to a *type slice*. This has special behaviour for contribution slices and errors.

**Basic Slices** If there are no errors, just use the analysed type slice, or if in synthesis mode use the synthesis slice.

**Contribution Slices: IMPL TODO** When synthesis and analysis slices exist, they can be combined here. Section 3.3.2 defines and explains this combination.

---

<sup>31</sup>Being part of the analysis slice, relevant to all sub-slices.

**Error Slices: IMPL TODO** Type inconsistency error checking can be extended to type slices via using type slice joins. The analysed and synthesised type slices are inconsistent if and only if a join exists. We can show both conflicting slices in this situation to explain the error (**Implement**). Additionally, syntax errors could have a slicing mechanism implemented here.<sup>32</sup>

### 3.3.4 Sum Types

Sum types are the hardest to work with, describe general design and difficulties in all the previous parts.

### 3.3.5 User Interface

Click on analysis or synthesis slices from context inspector

Show figures.

Implement UI from cursor inspector. Implement disabling of slicing.

## 3.4 Cast Slicing Implementation

To implement cast slicing, I replace casts between *types* by casts between *type slices*. The required type-indexed nature of type slices is already implemented, allowing these casts to be decomposed.

### 3.4.1 Elaboration

Cast insertion recursively traverses the unelaborated term, inserting casts to the term's statically determined type as stored in the **Info** data-structure and from the type as can be determined directly from the term.

For example, for list literals we can recursively elaborate the list's terms and join their static slices into **inner\_type**. Then, intuitively we would know during dynamics from these elaborated sub-terms that the list has a list type of **List(inner\_type)**:

Maybe a more diagrammatic option here

**Figure 3.12:** List Literal Elaboration

We can therefore construct the source type slices in these casts directly from the term during this traversal. (**TODO impl for atomic types like ints**)

Ensuring that all the type slice information from the **Info** map is retained and/or reconstructed during elaboration was a meticulous and error-prone process.

### 3.4.2 Cast Transitions

Section 2.1.2 gave an intuitive overview of how casts are treated at runtime. Type-indexed slices allows cast slices to be decomposed in exactly the same way.

---

<sup>32</sup>Not within the scope of this project. Empty slices are given instead.

list example

**Figure 3.13:** Ground Matching List

However, as Hazel only checks consistency between casts between *ground types* (fig. A.8), there are two rules where new<sup>33</sup> casts are *inserted* ITGround, ITExpand (fig. A.10). The new types are both created via a *ground matching* relation (fig. A.11) which takes the topmost compound constructor.

As we already store type slices incrementally, the part of the slice which corresponds *only* to the outer type constructor is just the outer slice tag.

### 3.4.3 Unboxing

When a final form (section 2.1.2) has a type, Hazel often needs to extract parts according to this type during evaluation. But due to casts and holes, this is not trivial [10].

For example, if a term is a final form of type list, then it could be either:

- A list literal.
- A list with casts wrapped around it.
- A list cons with indeterminate tail, e.g. `1::2::?`.

Additionally, when the input is not a list at all, it can return **DoesNotMatch**. Hence, allowing dynamic errors to be caught and also for use in pattern matching.

To allow for the varying outputs to unboxing depending on different patterns to match by, GADTs are used (**cite and explain**).

Various helper functions for unpacking type slices into it's sub-slices to significantly simplify pattern matching.<sup>34</sup> A uniform function for this could be implemented with a GADT, in a similar way to unboxing, but is not required.

### Hazel Unboxing Bug

While writing the search procedure I found an unboxing *bug* which would always *indeterminately match* a cons with indeterminate tail with *any* list literal pattern (of *any* length), even when it is known that it could never match. For example a list cons `1::2::?` represents lists with length  $\geq 2$ , but even when matching a list literal of length 0 or 1 it would indeterminately match rather than explicitly *not* match.

Pattern matching checks if each pattern matches the scrutinee with the following behaviour, starting from the first branch:

- *Branch matches?* Execute the branch.
- *Branch does not match?* Try the next branch.
- *Branch indeterminately matches?* Hazel cannot assume the branch doesn't match so cannot move on and must safely stop evaluation here classifying the entire match as an indeterminate term.

---

<sup>33</sup>As opposed to being derived from decomposition.

<sup>34</sup>These differ from matching functions, which also match the dynamic type to functions, lists etc.

Figure 3.14 demonstrates a concrete example which would get stuck in Hazel, but does *not* need to.

See PR example

**Figure 3.14:** Pattern Matching Bug

I reported and fixed this bug and added additional tests to ensure the bug never reappears. A PR was merged into the dev branch (**pending**).

### 3.4.4 User Interface

Mainly talk about the Model-view architecture and passing the cursor into the evaluator view to allow clicking on casts in evaluation result/stepper.

Difficulties in ensuring id tags for slices are not subtly aliased during elaboration and evaluation. This caused problems in selecting slices with UI. Look through commits to give example

## 3.5 EV\_MODE Evaluation Abstraction

This section describes in detail the evaluator abstraction present in hazel, which allows ...

Very complex!!! The reader could skip this section, it is purely technical.

## 3.6 Indeterminate Evaluation

Dynamic type errors may only occur when an expression is given *specific* inputs. However, a dynamic error is accompanied by an evaluation trace, which is often a *useful debugging aid* [29]. When debugging static type errors, traces leading to a corresponding dynamic error are normally *unavailable*.<sup>35</sup> This section concerns the building blocks leading up to a search procedure that finds inputs which lead to dynamic errors *automatically*.

Seidel et al. [20] provides an algorithm for this in OCaml and provides evidence for the usefulness of traces via a *user study*. This algorithm *lazily* narrows hole terms non-deterministically to a *least specific* value based on its expected type in the context it was used. For example, if a hole is used within the (+) operator, it is non-deterministically instantiated to an integer. **(give better example with lists)**

In Hazel, we already have a notion of hole terms and can already run program with static errors, with runtime type information being maintained by runtime casts. This section introduces *indeterminate evaluation* as a natural analogue to Seidel’s idea: to *lazily* narrow holes during evaluation to *least specific* values by exploiting the runtime type information available within Hazel’s runtime casts. My implementation extends Seidel’s to consider more classes of expressions<sup>36</sup> and differs mechanically in many ways due to language differences and fundamental design differences.<sup>37</sup> Notably, indeterminate evaluation is a *generic* evaluation method, not specifically relating only to searching for cast errors, which is covered in section 3.7.

This section covers the following, answering each question:

---

<sup>35</sup>As an ill-typed program will not run.

<sup>36</sup>Notably, sum types.

<sup>37</sup>Differences, and Hazel-specific challenges are noted throughout. **(ENSURE THIS!)**

3.6.1 How should we resolve the non-determinism in instantiating holes *fairly*? How can the search order be abstracted? Unlike Seidel’s approach, my implementation is *fair*: exhaustively considering all possibilities<sup>38</sup>, and allows search methods that avoid non-termination<sup>39</sup>.

3.6.2 Describes an algorithm for indeterminate evaluation. Is every possibility explored fairly?

?? How can *per-solution* state be maintained irrespective of evaluation order?

3.6.4 Discusses hole instantiation and substitution. What does lazy instantiation actually entail, when exactly should a hole be instantiated? Which hole<sup>40</sup> should be instantiated in order to continue evaluation to make progress? How should holes be substituted with their narrowed values; the same hole may exist in multiple locations within the expression?

3.6.5 How to use the evaluation abstraction (??) to perform just one evaluation step?

3.6.6 Finally, I consider Hazel-specific problems. Once we know which hole to instantiate, how can we get it’s *expected type*? Hazel’s lazy treatment of pushing casts into compound data types means not all such holes will be wrapped directly in casts. Additionally, the case of pattern matching is difficult, allowing holes to be *non-uniformly* cast to *differing types*. How can holes be instantiated in these situations?

As always, a UI is implemented in section 3.6.7.

### 3.6.1 Resolving Non-determinism

To model infinite non-determinism I decide to use a *monadic* high-level representation, and represent infinite solutions with sequences from Jane Street’s `Base.Sequence`. I choose this due to it’s *uniform*<sup>41</sup> and familiar workings for other developers in the codebase.

This sections describes an abstract DSL which abstracts the notion of non-determinism and the concrete search ordering. It’s *module type* of combinators is `Nondeterminism.Search`. Section 3.7.3 discusses the actual implementations of this interface, giving three different searching procedures.

#### Alternatives

Section 2.1.4 considered multiple ways to represent non-determinism. The other options were:

**Direct implementation:** This would not allow for easily abstracting the search order and would obfuscate the workings of the indeterminate evaluation and instantiation algorithms.

**Effect handlers:** Multiple continuation effect handlers were not supported by JSOO<sup>42</sup> (cite),

---

<sup>38</sup>For countable types.

<sup>39</sup>For example, if one particular instantiation leads to an infinite loop in code.

<sup>40</sup>There may be multiple.

<sup>41</sup>Many other types use the monadic return/bind interface. Lists and Options for example.

<sup>42</sup>An important dependency of Hazel.

**Continuations:** Directly writing continuations is difficult and generally unfamiliar to OCaml developers (cite).

**Optimised DSL** : Introducing a formal DSL including optimisations, such as the proposed Tagless-Final DSL [27, 14], is very complex.

## Monadic Non-determinism

To recap, in a monadic model of non-determinism we have three operations on monads  $m('a)$ :

- **return** :  $'a \Rightarrow m('a)$ , injects a single solution into it's non-deterministic monadic representation.
- **bind** :  $m('a) \Rightarrow ('a \Rightarrow m('b)) \Rightarrow m('b)$ , corresponding to a conjunction of choice. Given possibilities from  $m('a)$ , each leading to more possibilities in  $m('b)$ : **bind** conjoins all the non-deterministic possibilities from  $m('b)$ .
- **fail** :  $'a \Rightarrow m('a)$ , representing no solution, no choices are possible.
- **choice** :  $m('a) \Rightarrow m('a) \Rightarrow m('a)$ , a disjunction of choice: either solutions are possible. Represented infix by  $<| |>$ .

These satisfy the before mentioned laws (section 2.1.4). And we can define a host of other useful constructs from these:

- **map** :  $m('a) \Rightarrow ('a \Rightarrow 'b) \Rightarrow m('b)$ . Represented infix by  $>>|$ . Where  $m >>| f = m >>= (x \Rightarrow f x)$ . Mapping represents performing a transformation on all possible solutions.
- **join** :  $m(m('a)) \Rightarrow m('a)$ , where  $join(m) = m >>= (x \Rightarrow x)$ . (**todo, give intuition for join**).
- **once** :  $m('a) \Rightarrow option('a)$ , extracts any one solution, if one exists. This can be used to efficiently model *don't care* non-determinism, where if one possibility fails, then we know all others fail also.
- **run** :  $m('a) \Rightarrow Sequence.t('a)$  produces a lazy list of all solutions.
- **guard** :  $bool \Rightarrow m(unit)$ , represents success, defined by `code(false) = fail` and `code(true) = return(())`. When chaining binds, if any guard bind fails, then the whole computation fails.
- **ifte** :  $m('a) \Rightarrow ('a \Rightarrow m('b)) \Rightarrow m('b)$ . This corresponds to Mercury's interpretation of an if-then-else construct [3]. Where `ifte(c)(thn)(els)` executes the `els` only if the conditional `c` fails initially. Otherwise it binds the results of the in the `thn` branch. Importantly, if the conditional fails on backtracking, the `els` branch is *not* computed. Hence, it is put to good use for explaining failure of the conditional.

Stream model here, see [44]? Use arrows to indicate DFS.

**Figure 3.15:** Streams require Depth-First Search

### Abstracting Search Order: Tree Model

Typical stream-based models of non-determinism [53] only admit the possibility of depth-first search (DFS). Streams provide no way of remembering choice points and backtracking before finishing a computation.

Instead, a model of non-determinism using *trees* allows for nested choices. These trees can be traversed in various orders, such as breadth-first search (BFS)[44].

Tree of choices, use arrows to indicate breadth first search.

**Figure 3.16:** Tree of Choices with Breadth-First Search

To retain the possibility of failure, forests (lists of trees) can be used, with the empty list being failure.

Use same example as BFS above (pairs/choose function, i.e. instantiating tuples).

**Figure 3.17:** Forest Defined Using `wrap`

A combinator, `wrap`, allows for the programmer to control directly what constitutes a *fork* in the tree as suggested by Spivey [35]. Previous models would uniformly take each use of the choice operator as a fork, permitting less control. In essence, this allows for some notion of *cost*<sup>43</sup> for each solution to be directly encoded in the algorithm.

Implementations for DFS, BFS, and bounded DFS are given in section 3.7.3. In each case, the stream of solutions produced by `run` will return in the corresponding search order.

### Fairness in Infinite Choice & Conjunction

Previously

**Fair Choice:** Consider the choice  $m <| |> n$ , if  $m$  has infinite solutions. When using *append* to represent choice for sequences *cite*, then  $m <| |> n = m$ <sup>44</sup>. No solutions of  $n$  will be encountered upon running through this choice. But *append* is a perfectly valid definition of choice as according to the specified laws.

To ensure each possible solution is returned in finite time, it is useful to introduce fair choice. A fair choice computation will always return *every* possible answer. For the *append* example above, any form of *interleaving* can represent fair choice. **Cite fair choice, e.g. kiselyov?**

Fair choice is denoted by  $<|>$ . Figure fig. 3.18, shows how two infinite choice trees for non-negative and negative integers respectively would be appended vs interleaved fairly.

---

<sup>43</sup>The depth of the node in the tree.

<sup>44</sup> $m$  never ends to start appending  $n$ .

**Figure 3.18:** Unfair vs Fair Choice

1 -! (1, 1), (1, 2), ... 2 -! (2, 1), (2, 2), ...

**Figure 3.19:** Unfair vs Fair Conjunction

**Fair Conjunction:** Similarly, conjunction is not fair. For a computation  $(m \ll n) \gg= f$ , if  $m \gg= f$  is infinite, then only these might be returned. For example, binding sequences is typically defined via concatenating and mapping:  $m \gg= f = \text{concat}(m \gg | f)$ .

The use of unfair choice (`append`) leads to unfairness in `bind`. A fair conjunction would use fair choice instead.

Fair conjunction is denoted by  $\gg-$ . Figure 3.19 demonstrates how *pairs* of natural numbers can be generated fairly using *fair conjunction*.

These fair combinators satisfies the original non-determinism and monad laws up to the ordering of results. **Spivey says  $\gg-$  is not associative? Not sure I agree?**

## Recursive Functions

As OCaml is strict, to allow for easier I define a shorthand lazy application function `apply(f, x)` defined by `return(x) >>= f`. This is equivalent to regular application up to laziness. Represented infix by `|>-`. This allows the writing of recursive functions directly resulting in infinite choices without OCaml's strictness leading to infinite recursion.

**TODO: Do I need a fixed point operator? it seems hard to get this working for BFS!**

### 3.6.2 A Non-Deterministic Evaluation Algorithm

In Hazel, for any term  $d$ , we have four situations, for which indeterminate evaluation performs the following rules:

- $d$  is a final value.  
Return the value as a possible result.
- $d$  is an indeterminate final term.  
Some of these terms contain holes.<sup>45</sup> Non-deterministically instantiate these holes lazily and *fairly* try indeterminately evaluating each resulting term.
- $d$  is not final. Therefore a (deterministic) step is possible.  
Step to the new term  $d'$ . Indeterminately evaluate  $d'$ .
- There was an *evaluator exception*.  
Fail.

Instantiation can be represented by a *non-deterministic* function `instantiate`, discussed in detail in section 3.6.4:

`Instantiation.instantiate : Exp.t => m(Exp.t)`<sup>46</sup>

<sup>45</sup>Not all, indeterminate terms also arise from static or dynamic errors.

<sup>46</sup>Details & types relating to state and environment threaded through evaluation are omitted here for clarity. Therefore, these signatures differ from the code.

Classifying the term  $d$ , into values, indeterminate terms, and expressions with a possible step is done by a *deterministic* function `take_step`, discussed in section 3.6.5:

```
OneStepEvaluator.take_step : Exp.t => TryStep.t
```

To allow for multiple searching methods, the algorithm is placed within a *functor* (**cite**), which takes a searching method, `S : Search`, with the previously described signature (section 3.6.1). Using `S`, the algorithm is defined in fig. 3.20.

```
module Make = (S: Search) => {
  module Instantiation = Instantiation.Make(S);
  open S;
  open S.Infix;

  let rec values = (d: DHExp.t) : S.t(DHExp.t) => {
    let step = OneStepEvaluator.take_step(d);
    switch (step) {
    | BoxedValue => return(d)
    | Indet =>
      d |>- Instantiation.instantiate
        >>- values;
    | Step(d') => d' |>- values;
    | exception (EvaluatorError.Exception(_)) => fail
    };
  };
};
```

**Figure 3.20:** Indeterminate Evaluation to Values

### 3.6.3 Threading Evaluation State

In order to track statistics for use in the evaluation, state must be threaded through indeterminate evaluation. State tracked includes, on a *per-solution* basis.<sup>47</sup>

- Trace length: number of steps performed to get to this solution.
- Number of instantiations performed to get to this solution.

So instead of threading only the solutions, `DHExp.t`, I also thread the state, `(DHExp.t, IndetEvaluatorState.t)`, updating according depending on the branch taken.

Additionally, Hazel evaluates expressions in an global environment (`env : Environment.t`) which must also be passed down, but does not change after performing a step.

### 3.6.4 Hole Instantiation & Substitution

There are three key problems to solve in order to instantiate terms.

---

<sup>47</sup>Hazel also uses the state to track other interesting features: *Probes* and *Tests*. These are complex, making use of mutability, but are outside the scope of this project. However, my code still maintains this state correctly **TODO**.

One example with a cast error. One example with one holes. An example with multiple holes. An example where the holes don't matter.

**Figure 3.21:** Where Does Indeterminateness Originate?

### Choosing which Hole to Instantiate

An indeterminate term may contain *multiple* holes or even *no* holes. Which hole needs to be instantiated in order to *make progress*?

A term is concluded to be indeterminate if some part of it is indeterminate, as according to the rules in 2.1.2. If those corresponding sub-parts were instead a value, then the whole term would be a value. Recursively applying this logic, there will be a collection of terms where indeterminateness *originates*. These will either be holes or erroneous terms. If they are holes, then instantiating these may will either allow evaluation to continue or directly turn the overall term into a concrete value. Figure 3.21 demonstrates some examples of the possible situations.

Hazel's transition semantics specifies these rules, and careful use of the evaluation abstraction allows propagating the terms where indeterminateness originate (those which output the rule **Indet** in transition). To simplify, I consider and instantiate only the *first* hole where indeterminateness originates at a time. Should multiple need to be instantiated to progress, it will simply instantiate one hole, then fail to evaluate, then instantiate another, then try evaluate again, etc.

### Synthesising Terms for Types

Suppose we know which hole to instantiate and to which type (section 3.6.6). How do we refine these holes *fairly* and lazily, to their *least specific* value that allows evaluation to continue?

Some types are *atomic* and must be instantiated to (possibly infinite set) of concrete types:

**Booleans:** Simple binary choice: `return(true) <|> return(false)`.

**Integers:** Integers are countable, so can be enumerated, for example, by constructing the tree in fig. 3.22. Of course, OCaml integers are not arbitrary precision, so not every mathematical integer is represented here; in the future, Hazel might use arbitrary precision integers.

```
let rec ints_from = n => return(n) <|> wrap(n + 1 |>- ints_from)
let nats = ints_from(0)
let negs = ints_from(1) >>| n => -n
let ints = nats <|> wrap(negs)
```

SHOW TREE HERE

**Figure 3.22:** Enumerating Integers

**Strings:** A string is either *empty* or is a string with a first character from a finite set. We can recursively wrap all strings, prefixed by each character. See fig. 3.23:

```

let chars = // Every single letter string considered
let rec strings = () => return("")
  <||> wrap(chars >>= chr =>
    ((() |>- strings) >>- str =>
      chr ++ str))

```

SHOW TREE HERE, also check impl

**Figure 3.23:** Enumerating Strings

**Floats:** Every float can be represented by a (or multiple) rational number(s). Therefore, generating every rational number will then performing float division, will generate every float. Again, this does not actually generate every rational due to OCaml’s fixed-precision integers, and hence will not generate every float. See section 4.6.9 for further discussion.

Other types are *inductive*, these can be represented indirectly by lazily instantiating only their *outermost* constructor:

**Lists:** Any list can be directly represented as either the empty list, `[]` or a cons `? :: ?`. We do not need to generate every list directly.

**Sum Types:** Enumerate each of the sum’s constructors with their least specific value.

**Functions:** A function can be represented with it’s least specific value by `λ?. ?`. However, to allow functions to be used it is useful to instantiate the pattern to the wildcard pattern `‘_’`. The function may then be applied to any value. This therefore only generates *constant* functions, which is all that is required to find cast errors. But, extensions to program synthesis (section 5.2.5) would require more sophisticated function instantiation.

One might state that atomic types could be represented inductively. For example, every string of prefix `s` could be represented by `s ++ |dyn|`. However, Hazel does not currently treat these inductively; there is no way to destructure such a string, without first fully evaluating to a concrete value. The evaluation (section 4.6.9), discusses the implications of this in detail.

## Maintaining Correct Casts

Every hole instantiated must have originally been of the dynamic type. Therefore, that hole’s context would have *expected* it to be of the dynamic type. In order to maintain correct casts, from *actual* type to *expected* type, we must cast the every instantiation back to the dynamic type.

## Substituting Holes

Hole’s can be evaluated, and may also be duplicated, or be added to closures, before they are required to be instantiated. How can we consistently substitute these holes for their instantiations?

Figure 3.24 shows how a hole  $?_1$  can duplicated during evaluation and also bound within an closure.

Bbbb

**Figure 3.24:** Duplicated Holes

Hole substitution was described as part of the Hazel. Unexpectedly, the main Hazel branch did not yet implement it. Full implementation of *metavariables* and *delayed closures* is complex. Therefore, I instead use the existing term ids to represent metavariables, and ensure these ids are propagated correctly throughout statics, elaboration, and evaluation.<sup>48</sup>

By matching these ids, we can substitute terms for holes consistently throughout the entire expressions. This *included* substituting the holes eagerly inside closures, followed by evaluating the closure bindings to values, a required invariant.

### 3.6.5 One Step Evaluator

The step evaluator uses the evaluation abstraction to create an *evaluation context* from a term. **REF** Decomposing it into an object containing:

- An evaluation context, with a *mark* inserted in place of the sub-term which is evaluated according to the transition rules.
- The environment under which the sub-term is evaluated.
- The kind of rule that was used (e.g. substitution, addition, etc.).

Maintaining this information allows the indeterminate evaluation method to treat different steps differently. For example a search procedure might wish to extract only the steps which were substitutions, in order to produce a compressed execution trace.

### 3.6.6 Determining the Types for Holes

If we know which hole to instantiate, how do we know which type to instantiate it to?

For efficiency, my implementation both determines *which hole*, and it's *type information* during the same pass.

#### Directly from Casts

Most of the time, a hole is directly surrounded by a cast, whose type information can be used to perform an instantiation.

---

<sup>48</sup>A huge portion of the code-base required checks.

An example step leading to a specific eval obj.

**Figure 3.25:** `EvalObj.t` Example

## Cast Laziness

However, it is *not* always the case that a hole which needs to be instantiated is surrounded by a cast. For efficiency reasons, Hazel treats casts over compound data-types lazily, for example, casts around a tuple will only be pushed inside upon usage of a component of the tuple.

Therefore, in order to actually instantiate these into values directly, casts must be pushed inside compound data *eagerly*. **TODO IMPL**

However, when detecting cast errors, it is possible to maintain lazy casts by extending Hazel’s cast failure checking. Section 3.7.1 discussed this in more detail.

## Pattern Matching

Does a hole even have only one possible type?

The introduction of (dynamic) pattern matching actually allows terms to be matched against *non-uniform* types if the scrutinee is dynamic. In section 3.6.6, if `term` is an integer 0 then it returns 0, but if it’s the string “one” then it returns 1. Hence instantiating `code` to either an int or string might allow progress.

```
let term : ? = in case term — x::xs => x — 0 => 0 — "one" => 1 end
```

Hazel implements this by placing casts on the *branches*, rather than the scrutinee. Therefore, we can collect each of these possible types from the casts, and wrap them around the scrutinee, continuing evaluation accordingly.

## Extended Match Expression Instantiation

An interesting extension was attempted to improve code coverage of the instantiations **ref branch**. Given patterns are known, it is possible to instantiate holes according to not only the types, but also the *structure* of each pattern. This allows the instantiation to prioritise searching along each branch.

Hence, we could try instantiating the match scrutinee with least specific versions which match the patterns on each branch, e.g. `?::?` for `x::xs`. i.e.

To implement this, (**TODO**) the scrutinee needs to be matched against a pattern *and* instantiated at the same time. Crucially, instead of just giving up during indeterminate matches, the indeterminate part can be instantiated until it matches.

**Figure 3.28:** Combining Matching and Instantiation

However, this is not always enough to actually *allow* destructuring using that branch in a match statement. The possibility that *more specific* patterns could be present above the current

Show how indeterminate matches cause a list to try increasing lengths by repeatedly instantiating it’s tail...

**Figure 3.26:** Instantiating a Scrutinee

```
case ?::? | [] => [] | x::xs => xs
```

**Figure 3.27:** Branch-Directed Instantiation

NOT  $x::xs$  is  $[]$  NOT  $[\_]$  is  $[]$  or  $?::?::?$  Not 1 is the integers excepting 1 etc.

**Figure 3.30:** Not Instantiations

branch means the resulting instantiation might still be result in an indeterminate match. For example, the following would be an indeterminate match:

case  $?::?$  |  $[] \Rightarrow []$  |  $x::y::[] \Rightarrow []$  |  $x::xs \Rightarrow xs$

**Figure 3.29:** More Specific Matches

To solve this, we can introduce least specific instantiations that do *not* match a pattern. These will generally not be representable by only *one* term. For example:

The use of inequalities here can become inefficient, and representing cases like *not 1* result in infinite search-spaces. Extending this to a full-blown SMT solver would be beneficial, see ??.

### 3.6.7 User Interface

# Chapter 4

## Evaluation

**Should I put proposed implementation plans and improvements here or in implementation??**

Evaluation Here.

Evaluate small scope hypothesis for this problem. Note that small inputs don't necessarily correlate with small evaluation traces.

### 4.1 Goals

i.e. Project Proposal. But make it with more clarity, i.e. 'Most Type Errors Admit Witnesses' Completeness etc. most of Hazel...

### 4.2 Hypotheses

Various hypotheses for results, mentioned below.

### 4.3 Program Corpus Collection

**I need a corpus of programs with type errors and a corpus of programs with annotations (which may be well-typed). Currently have neither!! Think I might need help with this...**

Both the above could be transpiled from OCaml, ill-typed ones by just ignoring all types (though this adds some bias to the search procedure, by ignoring partially annotated examples or annotated but ill-typed situations, but it *should* be roughly ok). But sum types etc. may be harder to transpile.

#### 4.3.1 Methodology

#### 4.3.2 Alternatives

OCaml → Hazel transpiler

## 4.4 Effectiveness Analysis

### 4.4.1 Search Procedure

#### Witness Coverage

Describe reasons for failure in next section

#### Code Coverage

Were some branches not taken? ‘Solvable’ via symbolic execution

#### Trace Size

Larger trace sizes are harder to comprehend? Cite...

#### Cast Slice Size

Common complaints on error slices are large slice sizes. cite... Does this correlate with trace size?

### 4.4.2 Type Slicing

#### Correctness

?

#### Code Slice Size

Compare large theory slices with the ‘simplified’ slices.

## 4.5 Performance Analysis

### 4.5.1 Search Procedure

#### Time

#### Space

Lazy list stuff in particular...

### 4.5.2 Slices

#### Time

Very slice when used continuously... This might be due to bad design or bugs?

## Space

Compare with using using ‘Typ (slices turned off). Compare with old implementation (if possible)

Cast slices should be small as they only use sub-parts of terms and mostly exist at the leaves, or are incremental parts (i.e. to [?]). Compare the slice size of *casts* vs *type* slices.

## 4.6 Critical Analysis

### 4.6.1 Slicing

Which constructs are ignored in simplified slices? Why? Do they have the biggest impact on size?

Discuss the usability aspects of the 4 different type slicing ideas. Discuss

### 4.6.2 Structure Editing

Statics are recalculated upon edits and even cursor movement in Hazel. The previous results show that slicing is a *relatively expensive* operation, and not so suitable for such a rapid use case. In this section I discuss ideas for reducing the recalculation during local edits. **Check out Hazel’s incrementalisation efforts too to see if they help**

The Hazel structure editor allows efficient<sup>1</sup> updating of the external syntax tree via the use of a zipper. It would make sense to extend this zipper idea into the abstract syntax tree and its statics (typing information), allowing allow local changes to propagate to local changes (and type changes) in the AST zipper. Some local changes can propagate type changes *non-locally* (e.g. inserting a new binding) which would require extensive recalculation of the typed AST, but these would be relatively rare (**provide evidence for this?**).

This would require an entire rewrite of the Hazel statics.

### 4.6.3 Cast Laziness

Annotations will create casts, but in many cases these annotations will never actually be used. i.e. on a product where only the 2nd element is ever used, a cast error on the 1st element is still caught. Eager casts catch these errors, lazy casts do NOT.

### 4.6.4 Cast Errors during Evaluation

Cast errors may appear during evaluation, but subsequently ignored as they may be discarded upon further evaluation. i.e. we get to a safe result, even though a cast error appeared on the way. It is debatable if this should count as an error. Should be easy to implement a version which catches this and do some tests?

### 4.6.5 Static-Dynamic Error Correspondence

How to find dynamic errors for specific chosen static errors. Works well for some types of errors (inconsistency ones). But not for ones like inconsistent branches, show how this could

---

<sup>1</sup>Constant time.

be extended. Indet evaluation still allows these to be witnessed, but they just don't actually go to a cast error.

### 4.6.6 Categorising Programs Lacking Type Error Witnesses

#### Non-Termination

The original procedure would get stuck on programs that loop forever. (To) Fix with iterative deepening.

However, substituting in closures and enforcing the invariant that the bindings must be values, can lead to non-termination. *Verify how fixed points are treated in closures.*

#### Repeated Instantiations

A hole being instantiated to a hole. Does this ever happen??

#### Dead Code

Search proc cannot reach, and failed cast detection would never find one there even if it existed (i.e. statically found).

#### Dynamically Safe Code

Code that is safe to run in all situations, but still exhibits a static type error.

#### Needle in a Haystack

Very specific input required from multiple hole instantiations. Combinatorial explosion makes this very hard to find (solve with coverage directed search, but this requires SMT solvers at least).

### 4.6.7 Non-Local Errors

Useful when type correct code written but used in the wrong way, i.e. write the wrong map function with @ still has a valid type. Especially prevalent with global inference.

### 4.6.8 Bidirectional Type Error Localisation

It is generally good. Find some cases where bidirectional type error localisation is wrong.

### 4.6.9 Improving Hole Instantiation

Make strings inductive!

To improve code coverage. i.e. Strings and Floats are annoying, SMT solvers could be used to help explore branches... Equality solvers in particular would be very useful and quite easy to implement, in particular for strings which are generally used via equality as opposed to lists which are used incrementally via pattern matching.

### 4.6.10 Combinatorial Explosion

State space gets very large as more holes are instantiated from other holes, i.e.  $[] \rightarrow [?] \rightarrow [?, ?] \rightarrow [?, ?, ?] \dots$

## 4.7 Cognitive Walkthrough: Debugging a Type Error

This actually answers the question of how this helps debugging a type error.

Demonstrate how a static error would arise, and be debugged by either using slicing or finding a dynamic error for the expression and using cast slicing.

Could do a cognitive walk-through for this?

# Chapter 5

## Conclusions

### 5.1 Conclusion

Conclusions Here.

### 5.2 Further Directions

Further directions here, referencing unsatisfactory results from Evaluation. Also various extensions.

#### 5.2.1 Extension to Full Hazel Language

Type functions, recursive types, deferrals

#### 5.2.2 UI Improvements, User Studies

Better UI.

Effectiveness gauge in the real world

#### 5.2.3 Cast Slicing

Cast slicing here doesn't extend the nice properties I have with type slicing: that a program slice will synthesise/analyse the same type. It might be possible to have a system that does?

The implementation differs by storing slices directly in the context, making analysis slices.

Also, the fact that cast slices are manipulated in evaluation is completely opaque to the user *unless* they step through manually. Ways to better represent this information exist (cast dependency graphs etc.)

#### 5.2.4 Proofs

PRimarily about the search procedure & casts.

Also about creating a *stronger* link between static type errors and runtime errors, what Hazel considers as a runtime error is somewhat unintuitive, see the points made in evaluation.

A formal property of what exactly a type error witness *is* which actually matches with the implementation would be nice.

### 5.2.5 Indeterminate Evaluation & Logic Programming

The idea of allowing holes to evaluate indeterministically allows for nondeterminism in evaluation. This could be harnessed to write non-deterministic algorithms themselves.

Consider adding a new construct which filters indet terms. Hazel already has a construct for testing expressions which exposes the success/failure to the user directly in the editor. A similar construct could filter all indet evaluations which result in the test being true. **Give an example for calculating permutations.**

Such programs would want extensive improvements to the efficiency of indeterminate evaluation and would probably want ways to customise the instantiation ordering/search direction via code.

This idea is basically similar to the idea behind Curry, with these holes being like free variables in Curry. The narrowing evaluation strategies would perhaps work for Hazel.

So we could have incomplete programs using holes. Then we could write constraints on these programs. Then we could run the program to synthesise results for these holes, i.e. generating programs by running the program! *Maybe find some research concerning program synthesis using logic programming? ‘Logic programming and program synthesis’*

Of course, the current instantiation method only generates constant functions, so would be useless for general program synthesis, e.g. one asserting that  $f(x) = x$ , but could be extended. Also, if  $x$  here has infinite number of values, again it would fail (would need to reason by SMT or extensionality etc).

Maybe even dependent types could add more fine grained specifications to instantiate by.

### 5.2.6 Search Procedure

#### Jump Trace Compression

#### Symbolic Execution & SMT Solvers

*More details in appendix* Pattern matching in particular already has discussion on integration with SMT solving in the Live Pattern Matching paper.

#### Ad-Hoc Polymorphism

Not in Hazel, but the search procedure can't deal well with it

#### Formal Semantics & Proofs

Was an uncompleted extension goal

### 5.2.7 Let Polymorphism & Global Inference

Errors with global inference errors are often more subtle, where trace visualisation really shines.

## **Constraint Slicing**

To allow slices to work with constraint solvers. One error slicing paper already does this.

## **Gradual Type Inference**

Miyazaki has a good paper on this. Seems like it could work well in Hazel, though at the loss of parametricity.

## **Localisation**

Bidirectional typing localisation is good, but global inference is bad. The search procedure could improve localisation and also give more meaning (traces, slices) to localisations.

# Appendix A

## Hazel Formal Semantics

This is the complete formal semantics for the Hazel *core calculus*. It is *gradually typed* so consists of both an *external language* and *internal language*.

**ADD THE USEFUL THEOREMS AND REF THROUGHOUT TEXT.** Add brief notes pointing out unusual features.

### A.1 Syntax

$$\begin{aligned}\tau &::= b \mid \tau \rightarrow \tau \mid ? \\ e &::= c \mid x \mid \lambda x : \tau. e \mid \lambda x. e \mid e(e) \mid \langle\!\langle e \rangle\!\rangle^u \mid \langle\!\langle e \rangle\!\rangle^u \mid e : \tau \\ d &::= c \mid x \mid \lambda x : \tau d \mid d(d) \mid \langle\!\langle d \rangle\!\rangle_\sigma^u \mid \langle\!\langle d \rangle\!\rangle_\sigma^u \mid d \langle \tau \Rightarrow \tau \rangle \mid d \langle \tau \Rightarrow ? \not\Rightarrow \tau \rangle\end{aligned}$$

**Figure A.1:** Syntax: *types*  $\tau$ , *external expressions*  $e$ , *internal expressions*  $d$ . With  $x$  ranging over variables,  $u$  over hole names,  $\sigma$  over  $x \rightarrow d$  *internal language* substitutions/environments,  $b$  over base types and  $c$  over constants.

## A.2 Static Type System

### A.2.1 External Language

$\boxed{\Gamma \vdash e \Rightarrow \tau}$   $e$  synthesises type  $\tau$  under context  $\Gamma$

$$\begin{array}{c} \text{SConst} \frac{}{\Gamma \vdash c \Rightarrow b} \quad \text{SVar} \frac{x : \tau \in \Gamma}{\Gamma \vdash x \Rightarrow \tau} \quad \text{SFun} \frac{\Gamma, x : \tau_1 \vdash e \Rightarrow \tau_2}{\Gamma \vdash \lambda x : \tau_1. e \Rightarrow \tau_1 \rightarrow \tau_2} \\[10pt] \text{SApp} \frac{\Gamma \vdash e_1 \Rightarrow \tau_1 \quad \tau_1 \blacktriangleright \rightarrow \tau_2 \rightarrow \tau \quad \Gamma \vdash e_2 \Leftarrow \tau_2}{\Gamma \vdash e_1(e_2) \Rightarrow \tau} \quad \text{SEHole} \frac{}{\Gamma \vdash \llbracket \cdot \rrbracket^u \Rightarrow ?} \\[10pt] \text{SNEHole} \frac{\Gamma \vdash e \Rightarrow \tau}{\Gamma \vdash \llbracket e \rrbracket^u \Rightarrow ?} \quad \text{SAsc} \frac{\Gamma \vdash e \Leftarrow \tau}{\Gamma \vdash e : \tau \Rightarrow \tau} \end{array}$$

$\boxed{\Gamma \vdash e \Leftarrow \tau}$   $e$  analyses against type  $\tau$  under context  $\Gamma$

$$\begin{array}{c} \text{AFun} \frac{\tau \blacktriangleright \rightarrow \tau_1 \rightarrow \tau_2 \quad \Gamma, x : \tau_1 \vdash e \Leftarrow \tau_2}{\Gamma \vdash \lambda x. e \Leftarrow \tau} \quad \text{ASubsume} \frac{\Gamma \vdash e \Rightarrow \tau \quad \tau \sim \tau'}{\Gamma \vdash e \Leftarrow \tau'} \end{array}$$

**Figure A.2:** Bidirectional typing judgements for *external expressions*

$\boxed{\tau_1 \sim \tau_2}$   $\tau_1$  is consistent with  $\tau_2$

$$\begin{array}{c} \text{TCDyn1} \frac{}{? \sim \tau} \quad \text{TCDyn2} \frac{}{\tau \sim ?} \quad \text{TCRfl} \frac{}{\tau \sim \tau} \quad \text{TCFun} \frac{\tau_1 \sim \tau'_1 \quad \tau_2 \sim \tau'_2}{\tau_1 \rightarrow \tau_2 \sim \tau'_1 \rightarrow \tau'_2} \end{array}$$

**Figure A.3:** Type consistency

$\boxed{\tau \blacktriangleright \rightarrow \tau_1 \rightarrow \tau_2}$   $\tau$  has arrow type  $\tau_1 \rightarrow \tau_2$

$$\begin{array}{c} \text{MADyn} \frac{}{? \blacktriangleright \rightarrow ? \rightarrow ?} \quad \text{MAFun} \frac{}{\tau_1 \rightarrow \tau_2 \blacktriangleright \rightarrow \tau_1 \rightarrow \tau_2} \end{array}$$

**Figure A.4:** Type Matching

## A.2.2 Elaboration

$\boxed{\Gamma \vdash e \Rightarrow \tau \rightsquigarrow d \dashv \Delta}$   $e$  synthesises type  $\tau$  and elaborates to  $d$

$$\begin{array}{c}
\text{ESConst} \frac{}{\Gamma \vdash c \Rightarrow b \rightsquigarrow c \dashv \emptyset} \quad \text{ESVar} \frac{x : \tau \in \Gamma}{\Gamma \vdash x \Rightarrow \tau \rightsquigarrow x \dashv \emptyset} \\
\text{ESFun} \frac{\Gamma, x : \tau_1 \vdash e \Rightarrow \tau_2 \rightsquigarrow d \dashv \Delta}{\Gamma \vdash \lambda x : \tau_1. e \Rightarrow \tau_1 \rightarrow \tau_2 \rightsquigarrow \lambda x : \tau_1. d \dashv \Delta} \\
\text{ESApp} \frac{\Gamma \vdash e_1 \Rightarrow \tau_1 \quad \tau_1 \blacktriangleright \rightarrow \tau_2 \rightarrow \tau \quad \Gamma \vdash e_1 \Leftarrow \tau_2 \rightsquigarrow d_1 : \tau'_1 \dashv \Delta_1 \quad \Gamma \vdash e_2 \Leftarrow \tau_2 \rightsquigarrow d_2 : \tau'_2 \dashv \Delta_2}{\Gamma \vdash e_1(e_2) \Rightarrow \tau \rightsquigarrow (d_1 \langle \tau'_1 \Rightarrow \tau_2 \rightarrow \tau \rangle) (d_2 \langle \tau'_2 \Rightarrow \tau_2 \rangle) \dashv \Delta_1 \cup \Delta_2} \\
\text{ESEHole} \frac{}{\Gamma \vdash \llbracket \cdot \rrbracket^u \Rightarrow ? \rightsquigarrow \llbracket d \rrbracket_{\text{id}(\Gamma)}^u \dashv u :: \llbracket \Gamma \rrbracket} \\
\text{ESNEHole} \frac{\Gamma \vdash e \Rightarrow \tau \rightsquigarrow d \dashv \Delta}{\Gamma \vdash \llbracket e \rrbracket^u \Rightarrow ? \rightsquigarrow \llbracket d \rrbracket_{\text{id}(\Gamma)}^u \dashv \Delta, u :: \llbracket \Gamma \rrbracket} \\
\text{ESAsc} \frac{\Gamma \vdash e \Leftarrow \tau \rightsquigarrow d : \tau' \dashv \Delta}{\Gamma \vdash e : \tau \Rightarrow \tau \rightsquigarrow d \langle \tau' \Rightarrow \tau \rangle \dashv \Delta}
\end{array}$$

$\boxed{\Gamma \vdash e \Leftarrow \tau \rightsquigarrow d : \tau' \dashv \Delta}$   $e$  analyses against type  $\tau$  and elaborates to  $d$  of consistent type  $\tau'$

$$\begin{array}{c}
\text{EAFun} \frac{\tau \blacktriangleright \rightarrow \tau_1 \rightarrow \tau_2 \quad \Gamma, x : \tau_1 \vdash e \Leftarrow \tau_2 \rightsquigarrow d : \tau'_2 \dashv \Delta}{\Gamma \vdash \lambda x. e \Leftarrow \tau \rightsquigarrow \lambda x : \tau_1. d : \tau_1 \rightarrow \tau'_2 \dashv \Delta} \\

# Project Proposal

## Description

This project will add some features to the Hazel language [1]. Hazel is a functional research language that makes use of gradual types to support unusual features such as: holes (code placeholders) to give type meaning to incomplete programs. Importantly for this project, all Hazel programs, even ill-typed or incomplete programs, are evaluable. This allows dynamic reasoning about ill-typed programs via evaluation traces with the potential to improve the user’s understanding of *why ill-typed programs go wrong*. See example below:

```
let rec sum : Int -> Int = fun n ->
  if n == 0 then
    true      // Type error statically caught and correctly localised
  else
    n + sum(n - 1)
in sum(2)
```

But evaluation is still possible; see below a (compressed) trace to a stuck value exhibiting a cast error:

$$\text{sum}(2) \mapsto^* 2 + \text{sum}(1) \mapsto^* 2 + (1 + \text{true}^{\langle \text{Bool} \Rightarrow \text{Int} \rangle})$$

This project aims to exploit further this potential by providing some extra features to both: aid with finding values/inputs that demonstrate why type-errors were found (type-error witnesses) and linking the evaluation traces back to source code. But is not expected to directly measure the usefulness of such evaluation traces themselves in debugging, nor is the design space for a Hazel debugger inspecting and interacting with traces to be explored.

Searching for type-error witnesses automatically is the main feature provided by this project, inspired by Seidel et al. [20]. The intended use of this is to automatically generate values (for example, function arguments) that cause ill-typed programs to ‘go wrong’ (lead to a cast error). More specifically, the search procedure can be thought of as evaluating a *special hole* which refines its type dynamically and non-deterministically instantiates itself to values of this type to find a value whose evaluation leads to a *general* cast error – ‘general’ meaning excluding trivial cast errors such as generating a value that doesn’t actually have the refined expected type.

Such a search procedure is undecidable and subject to path explosion, hence the success criteria (detailed below) does not expect witnesses to be provided in general, even if they do exist. Sophisticated heuristics and methods to limit path explosion to support large code samples is not a core goal.

Formal semantics of this procedure and associated proofs is an extension goal, consisting of preservation proofs and witness generality proofs (formalising the notion of generality mentioned previously).

Secondly, *cast slicing* will track source code that contributed to any cast throughout the cast elaboration and evaluation phases. In particular, this allows a cast involved in a cast error relating to a type-error witness to point back to offending code. This is expected in some sense to be similar to blame tracking [30], error and dynamic program slicing [41, 52], although these are not directly relevant for this project.

Work required for the creation of an evaluation corpus of ill-typed hazel programs, requiring manual work or creation of automated translation and/or fuzzing tools, is timetabled.

## Starting Point

Only background research and exploration has been conducted. This consists of reading the Hazel research papers [1] and various other related research topics including: gradual types, bidirectional types, symbolic evaluation, OCaml error localisation and visualisation techniques.

More research, into the Hazel codebase in particular, and concrete planning is required and is timetabled accordingly.

## Success Criteria

Core goals are the minimum expected goals that must be completed to consider this project a success. This corresponds to a working tool for a large portion of Hazel.

Extension goals will be timetabled in, but are relatively more difficult and not required for the project to be considered a success.

First, I give some definitions of terms:

- **Core Calculus** – The formal semantics core of Hazel as referred to by the Hazel research papers [15].
- **Basic Hazel** – A Hazel subset consisting of the core calculus, product and sum types, type aliases, bindings, (parametric) lists, bools, int, floats, strings, and their corresponding standard operations.
- **Full Hazel** – Hazel, including **Basic Hazel** plus pattern matching, explicit impredicative system-F style polymorphism and explicitly recursive types.
- **Core Corpus** – A corpus of ill-typed Hazel programs that are similar in complexity and size to student programs being taught a functional language, *e.g. (incorrect) solutions to the ticks in FoCS*. This will include examples in **Basic** or **Full Hazel** as required.
- **Extended Corpus** – A corpus of ill-typed Hazel programs that are larger in size, more akin to real-world code.
- **Evaluation Criteria** – Conditions for the search procedure to meet upon evaluation:
  1. Must have reasonable coverage – success in finding an *existing* witness which is correct and general.

2. Must find witnesses in an amount of time suitable for interactive debugging – in-line with build-times for a debug build of existing languages.

## Core Goals

- Success criteria for Cast Slicing – Cast slicing must be *correct* (slices must include all code involved in the cast) and work for *all casts*, including casts involved in cast errors. Informal reasoning in evidence of satisfying these conditions is all that will be required.
- Success criteria for the Search Procedure – The procedure must work for **Basic Hazel**, meeting the **Evaluation Criteria** over the **Core Corpus**. Analysis of some classes of programs for which witnesses could not be generated is also expected.

## Extension Goals

- Search Procedure Extensions – Support for **Full Hazel** under the same criteria as above.
- Search Procedure Performance Extensions – Meeting of the **Evaluation Criteria** over an **Extended Corpus**
- Formal Semantics – The specification of a formal evaluation semantics for the search procedure over the **Core Calculus**. Additionally, a preservation and witness generality proof should be provided.

## Work Plan

### 21st Oct (*Proposal Deadline*) – 3rd Nov

Background research & research into the Hazel semantics, cast elaboration, type system, and codebase. Produce implementation plan for cast slicing and the search procedure for the **Core Calculus**. This includes an interaction design plan, expected to be very minimal.

*Milestone 1: Plan Confirmed with Supervisors*

### 4th Nov – 17th Nov

Complete implementation of Cast Slicing for the **Core Calculus**. Write detailed reasoning for correctness, including plan for **Basic Hazel**. Add unit testing.

*Milestone 2: Cast slicing is complete for the **Core Calculus**.*

### 18th Nov – 1st Dec (*End of Full Michaelmas Term*)

Complete implementation of the search procedure for the **Core Calculus**.

*Milestone 3: Search Procedure is complete for the **Core Calculus**.*

### 2nd Dec – 20th Dec

Extension of both cast slicing and the search procedure to **Basic Hazel**.

*Milestone 4: Cast slicing & search procedure are complete for **Basic Hazel***

## 21st Dec – 24th Jan (*Full Lent Term starting 16th Jan*)

Basic UI interaction for the project. Drafts of Implementation chapter. Slack time. Expecting holiday, exam revision, and module exam revision. Should time be available, the **Formal Semantics** extension will be attempted.

*Milestone 5: Implementation chapter draft complete.*

## 25th Jan – 7th Feb (*Progress Report Deadline*)

Writing of Progress Report. Planning of evaluation, primarily including decisions and design of tools to be used to collect/create the **Core Corpus** and planning the specific statistical tests to conduct on the corpus. Collected corpus and translation method will be one of:

1. Manual translation of a small ill-typed OCaml program corpus into ill-typed Hazel.
2. Manual insertion of type-errors into a well-typed Hazel corpus.
3. Collection of a well-typed Hazel corpus.  
Tools: A Hazel type fuzzer to make the corpus ill-typed.
4. Collection of a well-typed OCaml corpus.  
Tools: OCaml -j Hazel translator/annotator which works with well-typed OCaml. A Hazel type fuzzer.
5. Collection of an ill-typed OCaml corpus.  
Tools: OCaml -j Hazel translator which works with ill-typed OCaml. *This would NOT be expected to be an implicitly typed Hazel front-end which maintains desirable properties like parametricity.*

*Milestone 6: Evaluation plan and corpus creation method confirmed with supervisors.*

*Milestone 7: Underlying corpus (critical resource) collected.*

## 8th Feb – 28th Feb

Implementation of the required tools for evaluation as planned. Some existing code or tools may be re-used, such as the OCaml type-checker.

*Milestone 8: **Core Corpus** has been collected.*

## 1st Mar – 15th Mar (*End of Full Lent Term*)

Conducting of evaluation tests and write-up of evaluation draft including results.

*Milestone 9: Evaluation results documented.*

*Milestone 10: Evaluation draft complete.*

## 16th Mar – 30th Mar

Drafts of remaining dissertation chapters. If possible, collection and evaluation of **Extended Corpus** using the same tools as the **Core Corpus**.

*Milestone 11: Full dissertation draft complete and sent to supervisors for feedback.*

## 31st Mar – 13th Apr

Act upon dissertation feedback. Exam revision.

*Milestone 12: Second dissertation draft complete and send to supervisors for feedback.*

## 14th Apr – 23rd Apr (*Start of Full Easter Term*)

Act upon feedback. Final dissertation complete. Exam revision.

*Milestone 13: Dissertation submitted.*

## 24th Apr – 16th May (*Final Deadline*)

Exam revision.

*Milestone 14: Source code submitted.*

## Resource Declaration

- Underlying Corpus of either: Well-typed OCaml programs, Ill-typed OCaml programs, Hazel programs. For use in evaluation. The required tools or manual translation to convert these into the ill-typed Hazel **Core Corpus** are detailed and allocated time in the timetable.
- Hazel source code. Openly available with MIT licence on GitHub [\[2\]](#).
- My personal laptop will be used for development, using GitHub for version control and backup of both code and dissertation. I accept full responsibility for this machine and I have made contingency plans to protect myself against hardware and/or software failure. A backup pc is available in case of such failure.
